PREFACE

The Third American Peptide Symposium in Boston on June 19-23, 1972, was attended by three hundred scientists including over sixty colleagues from other countries. The meeting was held at the Jimmy Fund Auditorium of the Children's Cancer Research Foundation. The keen interest in this Symposium was due to an unprecedented upsurge of scientific and industrial interest and involvement in peptides in the past few years.

The increasing interaction of traditional peptide chemistry with physically and biologically oriented disciplines was reflected in this Symposium by a series of invited lectures. NMR in the conformational analysis of polypeptides was reviewed by F. A. Bovey. Properties of antamanide were presented by Th. Wieland. R. A. Bradshaw elaborated on a comparison between nerve growth factor and insulin. Angiotensin was discussed in terms of its physiological roles by M. J. Peach and its conformations by P. Fromageot. K. Hofmann reported on the progress toward the synthesis of ribonuclease T_1. N. Izumiya illustrated the problems involved in synthesizing this protein by the solid-phase technique. The significance of the hypothalamic hormones in physiology and medicine was elucidated by R. Guillemin.* The precision and sensitivity of amino acid analysis was reviewed by S. Moore, and S. Udenfriend revealed a fluorometric assay in the picomole range. E. Gross structural relationships in peptides containing α,β unsaturated amino acids. Many thanks are extended to the invited speakers for their outstanding presentations and the efforts in preparing the manuscripts.

---

*Admirably presented by R. Burgus when hurricane Agnes prevented Dr. R. Guillemin's travel from Washington, D.C. to Boston.

The large number of contributions presented during the ten sessions of the meeting placed high demands on the individual presiding chairmen. Their skillful and excellent performance is gratefully acknowledged. Nine papers on *structure and conformation* emphasized the usefulness of NMR and especially the high potential of carbon-13 NMR. Studies on oxytocin, deamino lysine-vasopressin, proline-containing cyclic hexapeptides, and on model aromatic dipeptides, tetra- and pentapeptides were reported. Solvent exposure of peptide protons was determined by NMR. Particularly fruitful proved to be conformational analysis of cyclic peptides, and this was again part of the lively *forum discussion*. Discourses on synthetic problems, side-reactions during cyclization and chemical behavior alternated with those on biological aspects, in particular, antamanide, neurohypophyseal hormones, valinomycin and actinomycin. Nineteen contributions dealt with *solid-phase synthesis*. Methodical studies on modified solid supports, improved protecting groups, insoluble coupling reagent and active esters, and the use of oxidation-reduction condensation and *o*-nitrophenyl esters were reported followed by accounts on problems and difficulties. Long-chain solid-phase syntheses with target sequences as lysozyme or ribonuclease T_1 apparently experienced many difficulties. Improved solid-phase syntheses of LH-RH/FSH-RH and encephalitogenic peptides and preparations of valine-gramicidin B and C and of semisynthetic noncovalent protein (nuclease) complexes were presented. *Synthetic advances* by conventional methods in solution and *progress in synthetic procedures* were covered by sixteen papers. Complex syntheses of ribonuclease T_1, a porcine gastric inhibitory polypeptide and porcine proinsulin are very close to completion. Single crystals were obtained of $(Pro\text{-}Pro\text{-}Gly)_{10}$ and human ACTH was synthesized according to the corrected structure. Syntheses of hypothalamic hormones are currently pursued in many laboratories. Several novel amine protecting groups were disclosed. Amide protection, new catalytic agents, problems of racemization and of cystine peptide syntheses continue to be of interest. Broad coverage was given to biological aspects. Ten presentations in the session on *biologically active peptides* dealt with antamanide, scotophobin, tuftsin, nerve growth factor, vasopressins, biosynthetic actinomycins, fibrinogen peptides, bradykinin-potentiators, a polypeptide from the lung and a L-glutamine antimetabolite. An entire session with thirteen papers was devoted to *angiotensin*, its pharmacology, its *in vivo* generation, and its conformation as well as structure-activity

relationships and syntheses of inhibitors. *Hormonal messengers*, such as hypothalamic factors, β-lipotropin, cyclic AMP, and gastrointestinal hormones, and studies on structure and function of ACTH were presented in six papers. The eleven papers in the session on *analytical techniques* were concerned with amino acid analysis, fluorometric assay in the picomole range, sequence analysis by (a) mass spectrometry of hydrolysis mixtures, (b) thermal degradation, and (c) automated Edman degradation. Structure elucidation of viomycin and a human plasma alipoprotein were also covered. Probable future trends of the field were examined in a *forecast* at the end of the meeting.

The discussions were very lively and stimulating. The difficulties of preserving meeting discussions in print cannot easily be resolved. At the end of each chapter I have attempted to summarize various points of general interest raised during the discussions. The already large volume of the book required that these comments be brief. They were taken from the tape recordings without trying to identify individual discussants.

I am very indebted to all members of the Program Committee for their many valuable suggestions during the organization of the program and for their devoted help in editing manuscripts. R. Walter undertook the difficult task of editing the forum discussion on cyclic peptides.

Generous financial support to the Symposium fund has greatly assisted organizing the meeting. We wish to thank the following sponsors for their contributions: Abbott Laboratories; Armour Pharmaceutical Company; Ayerst Research Laboratories; Beckman Instruments, Inc.; Children's Cancer Research Foundation, Inc.; CIBA-GEIGY; Hoffmann-La Roche Inc.; Merck and Company, Inc.; Norwich Pharmacal Company; Pierce Chemical Company; Sandoz Pharmaceuticals; Schering Corporation; G. D. Searle and Company; and The Dow Chemical Company.

The Planning Committee entered into an appointive three-term membership system, and the terms of office of G. W. Anderson, M. Bodanszky, M. Goodman, R. B. Merrifield, M. A. Ondetti, and B. Weinstein expired. Their services are deeply appreciated. The new committee appointed Dr. R. Walter to organize the fourth symposium in New York.

ABBREVIATIONS

The abbreviations used in this book are listed below. For amino acid residues and several protecting groups they are those recommended by IUPAC-IUB Commission on Biochemical Nomenclature in Biochemistry 5, 1445, 2485 (1966); 6, 322 (1967); J. Biol. Chem. 241, 2491 (1966); 247, 977 (1972).

A I	Angiotensin I
A II	Angiotensin II
A II'	Angiotensin II amide ([Asn^1]-Angiotensin II)
AA	Antamanide
Abu	L-α-Aminobutyric acid
Ac	Acetyl
Acm	Acetamidomethyl
AcOH, HOAc	Acetic acid
Acpc	1-Aminocyclopentanecarboxylic acid (Cycloleucine)
ACTH	Adrenocorticotropin
$(Alk)_3N$	Trialkylamine, *t*-amine
apoLp-Gln II	Apolipoprotein II (Gln C-terminal)
AVP	Arginine-vasopressin
Boc	*t*-Butyloxycarbonyl
Bpoc	2-(*p*-Biphenylyl)isopropyloxycarbonyl
BPTI	Bovine pancreatic trypsin inhibitor
m-BrBzl	*m*-Bromobenzyl
o-BrZ	*o*-Bromobenzyloxycarbonyl
p-BrZ	*p*-Bromobenzyloxycarbonyl
Bu^iOCOCl	Isobutyl chloroformate
Bu^t	*t*-Butyl
Bz	Benzoyl
Bzl	Benzyl

CCD	Countercurrent Distribution
CD	Circular dichroism
Cha	β-Cyclohexylalanine
CHO	Formyl
4-CH_3OBzl (MeOBzl)	4-Methyloxybenzyl
2,6-Cl_2Bzl	2,6-Dichlorobenzyl
2,4-Cl_2Z	2,4-Dichlorobenzyloxycarbonyl
2,6-Cl_2Z	2,6-Dichlorobenzyloxycarbonyl
3,4-Cl_2Z	3,4-Dichlorobenzyloxycarbonyl
CM	Carboxymethyl (cellulose, Sephadex)
CP-B	Carboxypeptidase B
CT	Cobrotoxin
cyclic AMP	cyclic Adenosine-3',5'-monophosphate
Cys(Cm)	*S*-Carboxymethylcysteine
DCC, DCCI	Dicyclohexylcarbodiimide
DCHA	Dicyclohexylamine
DEAE	Diethylaminoethyl
DFP	Diisopropyl fluorophosphate
Dipmoc	Diisopropylmethyloxycarbonyl
DLVP	1-Desamino lysine-vasopressin, (1-(β-mercaptopropionyl]-lysine-vasopressin
DMF	Dimethylformamide
DMSO	Dimethylsulfoxide
Dnp	2,4-Dinitrophenyl
Dns	Dansyl, 1-dimethylaminonaphthalene-5-sulfonyl
DTP	2,2'-Dithiopyridine
Ec	Ethylcarbamyl
EDAC	*N*-Ethyl-*N*'-(3-dimethylaminopropyl) carbodiimide
EDTA	Ethylenediamine tetraacetic acid
EEDQ	*N*-Ethyloxycarbonyl-2-ethyloxy-1,2-dihydroquinoline
Et_3N, NEt_3	Triethylamine
EtOH	Ethanol
FDNB	1-Fluoro-2,4-dinitrobenzene
FSH	Follicle-stimulating hormone
FSH-RH	Follicle-stimulating hormone-releasing hormone
<Glu	Pyroglutamic acid, pyrroliá-2-one-5-carboxylic acid
GRF, GRH	Growth hormone releasing factor

GS-MS	Gas chromatography - mass spectrometry
GU	Goldblatt unit
HAA	Perhydro-antamanide
HDL	High density lipoprotein
HF*i*PA	Hexafluoro-2-propanol
HGH	Human growth hormone
HOAc, AcOH	Acetic Acid
HOBt	1-Hydroxybenzotriazole
HONSu, HOSu	*N*-Hydroxysuccinimide
HPT	Hexamethyl phosphoric acid triamide
Hyp	Hydroxyproline
*i*Noc	Isonicotinyloxycarbonyl
IR	Infrared spectroscopy
i.v.	Intravenous (injection)
LAP	Leucine aminopeptidase
LH	Luteinizing hormone
LH-RH, LRF	Luteinizing hormone - releasing hormone
LPH	Lipotropic hormone
LVP	Lysine-vasopressin
MA	Carbonic acid mixed anhydride (method)
Mbh	4,4'-Dimethyloxybenzhydryl
McBoc	1-Methylcyclobutyloxycarbonyl
Me	Methyl
βMe	β-Mercaptoethanol
3,4-Me_2Bzl	3,4-Dimethylbenzyl
MeIle	*N*-Methylisoleucine
MeLeu	*N*-Methylleucine
MeOBzl, 4-CH_3OBzl	*p*-Methyloxybenzyl
MeOH	Methanol
MePhe	*N*-Methylphenylalanine
MRF	Melanotropin releasing factor
MRIF	Melanotropin-release inhibiting factor
MSH	Melanocyte-stimulating hormone, melanotropin
NCA	*N*-Carboxyanhydride
Ncps	2-Nitro-4-carboxyphenylsulfenyl
NGF	Nerve growth factor
NHPH	Neurohypophyseal hormone
N^{π}-MeHis	*pros* Methylhistidine (*N* nearer to C^{β})
N^{τ}-MeHis	*tele* Methylhistidine (*N* away from C^{β})
NMR	Nuclear magnetic resonance spectroscopy

Nps	*o*-Nitrophenylsulfenyl
Nps-ACTH	*o*-Nitrophenylsulfenyl adrenocorticotropin
Nva	Norvaline
OBt	1-Hydroxybenzotriazole ester
OBzl	Benzyl ester
OBu^t	*t*-Butyl ester
OEt	Ethyl ester
ONb	*p*-Nitrobenzyl ester
ONo	*o*-Nitrophenyl ester
ONp	*p*-Nitrophenyl ester
ONSu	*N*-Hydroxysuccinimide ester
OPcp	Pentachlorophenyl ester
OPfp	Pentafluorophenyl ester
OPsp	*N*-5-(Polystyryl-4-methyloxycarbonyl)-imino-4-oximino-1,3-dimethyl-2-pyrazoline ester
ORD	Optical rotatory dispersion spectroscopy
OTcp, Ocp	2,4,5-Trichlorophenyl ester
PDE	3',5'-cyclic Adenosine monophosphate phosphodiesterase
PGC	Pyrolysis - gas chromatography method
Pht	Phthalyl
PI	Proinsulin
PLV-2	[Phe^2]-Lysine-vasopressin
PMA	Phenylmercuri acetate
PMR	Proton magnetic resonance spectroscopy
PRF	Prolactin releasing factor
Pro(4Br)	4-Bromo-L-proline
REMA	Repetitive excess mixed anhydride (method)
RNase T_1	Ribonuclease T_1
SPS, SPPS	Solid-phase peptide synthesis
TFA	Trifluoroacetic acid
Tfa	Trifluoroacetyl
tlc	Thin-layer chromatography
tle	Thin-layer electrophoresis
TMS	Trimethylsilane
Tms	Trimethylsilyl
Tos	Tosyl,*p*-toluenesulfonyl
TPCK	Tosylphenylalanine chloromethylketone
TPP	Triphenylphosphine

TRH, TRF	Thyrotropin - releasing hormone
Trt	Trityl, triphenylmethyl
TSH	Phyroid-stimulating hormone, Thyrotropin
Tyr(Ome)	*O*-Methyltyrosine
UV	Ultraviolet spectroscopy
Z	Benzyloxycarbonyl
Ztf	2,2,2-Trifluoro-*N*-benzyloxycarbonyl-aminoethyl

CHEMISTRY AND BIOLOGY OF PEPTIDES

NMR IN THE CONFORMATIONAL ANALYSIS OF POLYPEPTIDES, ESPECIALLY CYCLIC POLYPEPTIDES

F. A. Bovey. Bell Laboratories, Murray Hill, New Jersey 07974

SUMMARY--The application of proton and C-13 NMR to the study of the conformations of polypeptides, particularly cyclic polypeptides, is discussed. Proton NMR is considerably further developed for this purpose at the present time than C-13 NMR. Main chain conformations can be deduced from the J coupling of the α- and NH protons, together with information concerning internal hydrogen bonds from measurement of the NH resonance positions as a function of temperature, from observations of *cis-trans* isomerization of X-Pro peptide bonds, and from energy calculations. In C-13 spectroscopy, no coupling information is available and one must rely on chemical shifts, at least some of which (particularly in proline residues) appear to be sensitive to conformation. The use of NMR is illustrated for cyclic hexapeptides, for antamanide, and for oxytocin and its open chain precursor peptides.

INTRODUCTION

OF THE SPECTROSCOPIC METHODS useful for the study of polypeptide conformations, high resolution NMR has recently emerged as one of the most powerful. Many studies in our laboratory and in others have amply demonstrated that proton NMR (pmr) can provide large numbers of spectral parameters, i.e. chemical shifts and spin-spin couplings. If they could be fully interpreted, these data would give a fairly complete conformational picture of these molecules. As yet, such a

complete interpretation is usually not possible but nevertheless certain features of the spectra can be made to yield information concerning the main-chain conformations of polypeptides and oligopeptides. Of the latter, cyclic polypeptides, both synthetic and naturally occurring, have been the objectives of particularly intensive investigation in our laboratory[1] and in many others.

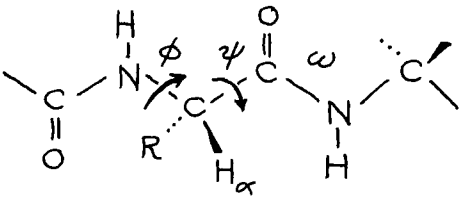
Limited C-13 NMR (cmr) data have also been recently published for several amino acids,[2] di- and tripeptides,[2] a cyclic polypeptide (gramicidin S),[3] a linear polypeptide (poly-γ-benzyl-L-glutamate),[4] a cyclic depsipeptide (valinomycin)[5] and a protein (ribonuclease A).[6] C-13 studies are in course of publication from our laboratory on oxytocin and its precursor peptides, valinomycin and its K^+ complex,[8] antamanide,[9] and antamanide-sodium complex.[10] I will mention certain aspects of this work today. In addition, C-13 investigations of synthetic cyclic hexapeptides, carried out in collaboration with Professor Blout's group at Harvard, are in course of preparation for publication. This work will be discussed in part in this presentation, and also in a separate paper by Dr. Deber. We may note also several other C-13 studies to be presented in this meeting, including one by Smith *et al.* on both oxytocin and deamino lysine vasopressin and their precursor peptides.

The greater part of the 15 years since natural abundance C-13 spectroscopy was first described[11,12] has been a period of extensive data collecting with relatively little interpretation in terms of structure or conformation. One reason for this state of affairs is the very large range of C-13 chemical shifts, over 350 ppm, or roughly 30 times the range usually observed for protons. This is in itself attractive, since it promises fine discrimination, but it has tended to baffle fundamental understanding, although there is a considerable body of empirical correlations. Another reason is that ^{13}C-^{1}H J couplings have not as yet proved particularly useful in conformational analysis, as ^{1}H-^{1}H couplings are, and in any case are banished from present day C-13 spectra by double irradiation in order to improve the signal-to-noise ratio. Thus, in polypeptide C-13 spectra we have only chemical shifts to help us. I will show, however, that these may be helpful and in fact can supply data which are not provided, or at best more ambiguously provided, in proton spectra.

Proton NMR

The proton parameters which can be most incisively interpreted in terms of main chain conformation, i.e. rotation angles, are as follows:

1. *The vicinal coupling of the C_α proton and the NH proton*, termed $J_{N\alpha}$, which can be interpreted in terms of a Karplus-like relationship to give the rotation angle ϕ:



$J_{N\alpha}$ is measured as the spacing of the NH multiplets, usually observed in the 1.5 - 2.5 τ range and appearing as doublets for all residues except glycine. An appropriate relationship has been found to be:

$$J_{N\alpha} = \begin{cases} 8.5\cos^2\phi' & (0° \leq \phi' \leq 90°) \\ 9.5\cos^2\phi' & (90° \leq \phi' \leq 180°) \end{cases} \qquad (1)$$

where ϕ' is the *dihedral* angle, not ϕ as defined by the 1966[13] or 1970[14] angle conventions.

2. *The temperature coefficient of the NH chemical shift* gives information concerning the participation of these protons in hydrogen bonds. Upfield shifts with increasing temperature are expected for protons capable of forming hydrogen bonds and are attributed to the breaking of an increasing fraction of such bonds. This dependence should be small for intramolecular hydrogen bonds but substantial for those capable of forming only external hydrogen bonds to solvent. The method is very useful but is not always straightforward. For example, the occasional observation of *negative* slopes instills caution.

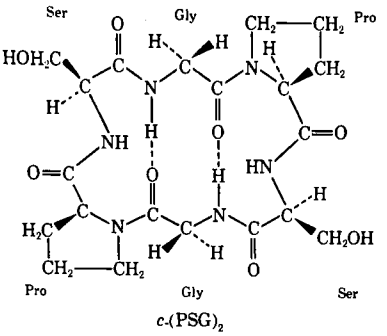
Observations of Cis-Trans Peptide Bond Isomerism. It is well known that because of the planar nature of the peptide bond, the angle ω must be either 0° (*trans*) or 180° (*cis*), major departures from these values being costly in terms of energy. The *cis* structure can normally be adopted only by N-substituted residues, i.e. prolines or (more rarely) sarcosine. The energy barrier separating the *cis* and *trans* conformations of X-Pro bonds is of the order

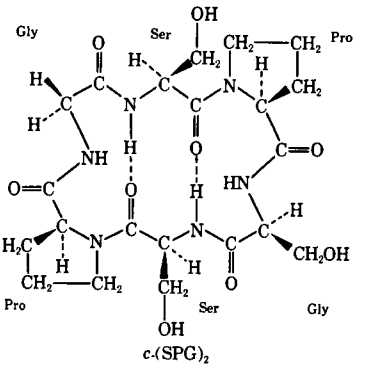
of 20 kcal. The nmr correlation of these familiar facts is the appearance of separate *cis* and *trans* spectra when both forms are present, owing to the relatively slow equilibration between them. Since most biological polypeptides contain proline and the more intriguing conformational behavior of synthetic polypeptides often depends on the presence of proline residues, this is an observation of major importance. Strong emphasis has been placed on proline in much of our work, both in pmr and cmr.

4. *Peptide NH Exchange Rate.* The NH proton exchange rate with hydroxylic solvents can be monitored analytically by observing NH peak intensity reductions in deuterated solvents, usually D_2O. More rarely, fast exchange rates can be measured in H_2O by peak broadening. It is a little difficult to know what to say about this type of study, which is, of course, an old and well established one for proteins, using isotopic tracers. It can be helpful when marked retardation of rate can be correlated with internal hydrogen bond formation, as observed, for example, by Stern, Gibbons, and Craig in their pioneering study of gramidicin S.[15] Like others, we have found it useful, but we have also found it to be erratic; for some compounds, rates have been observed to vary inexplicably by orders of magnitude between different preparations of the same polypeptide solution. We now treat results of such measurements with great reserve.

5. *Energy Calculations.* For simpler polypeptides, particularly if cyclic, NMR alone may be sufficient to yield a conformational structure fairly unambiguously. For more complex polypeptides, the NMR data alone, although very rich, cannot be completely and unambiguously interpreted in terms of conformation. *Ab initio* energy calculations are virtually impossible because of the large number of possible conformations. However, by incorporating NMR data into the energy calculations, it is found that self-consistent structures (or groups of structures) can be arrived at. This is done by eliminating from consideration all structures having one or more residues which do not correspond to the observed $J_{N\alpha}$ or to a low conformational energy.

Let us now look at a few applications of these methods. The use of criteria 1, 3 and 4 is well illustrated in the study of gramicidin S by Stern, Gibbons, and Craig.[15] We shall consider here two simpler hexapeptides:





These compounds illustrate well the typical features of the NMR spectra of cyclic polypeptides and turn out to exhibit some surprising conformational behavior; the conclusions drawn by NMR are fully supported by energy calculations.[16] In Figure 1 are shown the spectra of

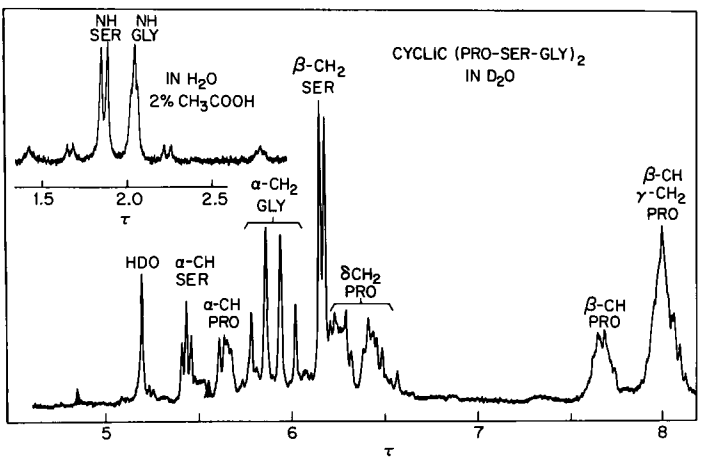


Figure 1: 220 MHz spectrum of *cyclo*(-Pro-Ser-Gly-Pro-Ser-Gly-) in D_2O and (upper left) in H_2O-CH_3COOH, 98:2 by vol.; 22°. The H_2O solution is made acidic to retard exchange of NH protons with solvent (ref. 17).

cyclo (-Pro-Ser-Gly-Pro-Ser-Gly-), abbreviated *c*-(PSG)$_2$, in D_2O and (inset) in H_2O.[17] From the spacings of the Gly NH "triplet" (actually a quartet from coupling to two Gly β protons) and the Ser NH doublet, $J_{N\alpha}$ is determined and limits for the φ angles for these residues are established. (There is, of course, no NH resonance for Pro residues, but this is not important as in this case φ is fixed at *ca.* 120° by the pyrrolidine ring.) In D_2O, the NH protons are exchanged for deuterium and these couplings cannot be measured, but the α-proton spectrum is now simpler to analyze. The assignments of the glycine and serine α-protons are shown in Figure 1; the former appear as an AB quartet in the asymmetric environment of the serine and proline residues; the latter is effectively a triplet, although actually the X part of an ABX system. The proline ring protons give a complex spectrum, the assignments being based on extensive previous study.[18-21]

In d_6-dimethylsulfoxide (d_6-DMSO), the spectrum (not shown) of *c*-(PSG)$_2$ is essentially similar to Figure 1; in this solvent, the NH protons are not exchanged and appear in the same relative positions as in Figure 2 (inset).

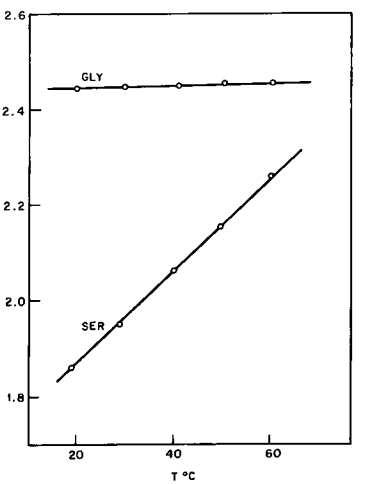

Figure 2: Temperature dependence of the Gly and and Ser NH protons of *cyclo*(-Pro-Ser-Gly-Pro-Ser-Gly-) in d_6-DMSO; 22° (ref. 17).

In Figure 2, the glycine and serine NH peak positions are plotted vs. temperature. The results strongly suggest that the glycine peptide protons participate in internal hydrogen bonds whereas those of the serine residues are externally hydrogen bonded; the relatively greater deshielding of the latter probably reflects principally the strong hydrogen bond acceptor properties of DMSO.

The observation of a single spectrum for each pair of like residues in *c*-(PSG)$_2$ demonstrates C_2 symmetry. The evidence for glycine NH hydrogen bonding together with the values of $J_{N\alpha}$ for the glycine (*ca.* 4.0 and 5.0 Hz) and serine (8.5 Hz) residues are compatible only with the conformations shown in Figure 3 in both water and DMSO.

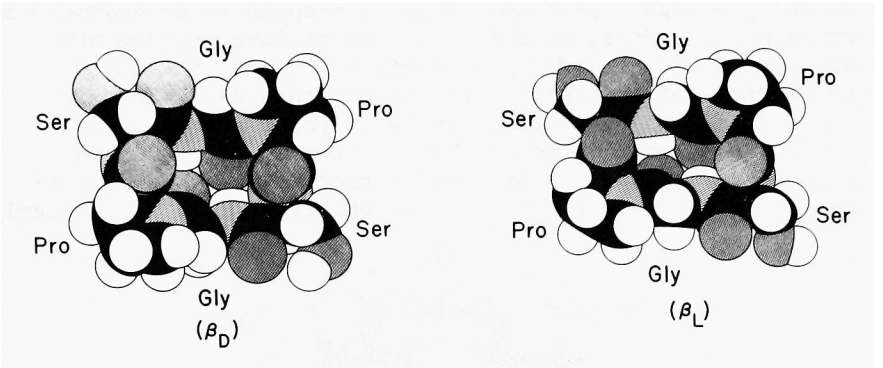

Figure 3: The β_D and β_L conformations of *cyclo*(-Pro-Ser-Gly-Pro-Ser-Gly-). Angles: all $\omega = 0°$;
β_D: $\phi_{Pro} = 290°$; $(\phi,\psi)_{Ser} = 240°, 210°$; $(\phi,\psi)_{Gly} = 330°, 60°$.
β_L: $\phi_{Pro} = 290°$; $(\phi,\psi)_{Ser} = 240°, 210°$; $(\phi,\psi)_{Gly} = 30°, 0°$.

In these structures, all peptide bonds are *trans* and the glycine and serine residues are in somewhat distorted antiparallel β-type conformations. That designated β_L has glycine angles appropriate for an L-residue β-structure, while in the β_D conformation the glycine residues have angles appropriate to a D-residue β-structure. Calculations[16] show these conformations to be of nearly equal energy, while the middle-range values of $J_{N\alpha}$ for both the glycine protons indicate an averaging of these couplings corresponding to rapid equilibration of the two forms. The two hydrogen bonds stabilizing this form involve glycine C=O and NH groups only.

The $\beta_D \rightleftarrows \beta_L$ conformations of *c*-$(PSG)_2$ are the principal but not the only ones present. The peptide proton spectrum (Figure 1, inset) shows minor resonances appearing as *equal pairs* of glycine NH triplets and serine NH doublets. (Related resonances can be seen upon close inspection of the α-CH region, e.g. near 5.5 τ.) Variation of temperature and solvent does not alter the relative intensities of these resonances, but does alter somewhat their ratio to the principal spectrum. They correspond to an *asymmetric* conformation, designated A, with one proline residue now *cis*, and the other *trans*, in equilibrium with the major symmetric conformation. Their temperature dependence is consistent with one intramolecular glycine NH hydrogen bond, the other glycine and both serine NH protons being exposed to solvent. A proposed structure for this conformation is shown in Figure 4. Its observation is particularly

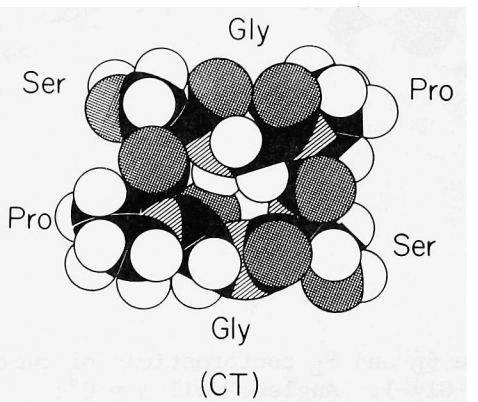

Figure 4: The A conformation of *cyclo*(-Pro-Ser-Gly-Pro-Ser-Gly-). Angles: Gly(NH H-bonded): ω = 180°; all other ω = 0°.

significant because it tells us that structures which appear to have C_2 (or higher) symmetry from the structural formula alone need not actually have such symmetry.

The retroisomeric hexapeptide *cyclo*(-Ser-Pro-Gly-Ser-Pro-Gly-), designated *c*-$(SPG)_2$, shows different conformational behavior from *c*-$(PSG)_2$. In H_2O, the NMR spectrum indicates a conformation similar to the β_L structure of the latter.[22] The β_D structure is excluded as its energy is substantially higher. The serine and glycine residues have now reversed roles, the serine NH being internally hydrogen bonded, as shown by its small temperature dependence (Figure 5), whereas the glycine NH protons are

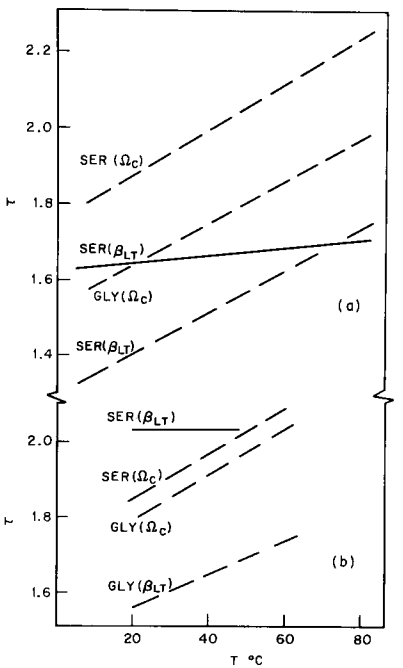

Figure 5: The temperature dependence of the chemical shifts of the NH resonances of *cyclo*(-Ser-Pro-Gly-Ser-Pro-Gly-) in (a) H_2O-CH_3COOH, 98:2 by vol.; (b) d_6-DMSO (ref. 22).

exposed to solvent. This conformer is designated β_{LT} and is shown in Figure 6 (top). A minor fraction of another symmetrical conformer can be detected in the spectrum. In d_6-DMSO solution this becomes the major conformation. Figure 7 shows the appearance of the NH spectrum as a function of solvent composition. The NH temperature dependence demonstrates that this second form has no internal hydrogen bonds; this observation and the $J_{N\alpha}$ values are consistent with a conformation, Ω_C, in which both proline residues are *cis* (Figure 6 bottom). It is strongly folded

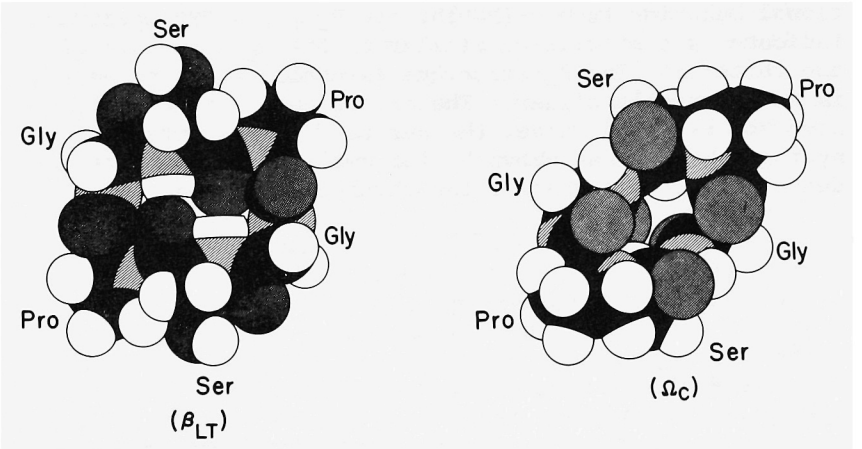

Figure 6: The β_{LT} and Ω_C conformations of *cyclo*(-Ser-Pro-Gly-Ser-Pro-Gly-). Angles for β_{LT}: all ω = 0°; $(\phi,\psi)_{Ser}$ = 30°, 330°, Pro ϕ = 300°; $(\phi,\psi)_{Gly}$ = 300°, 150°. Angles for Ω_C: $(\phi,\psi,\omega)_{Ser}$ = 25°, 325°, 180°; $(\phi,\psi)_{Pro}$ = 300°, 0°; $(\phi,\psi,\omega)_{Gly}$ = 240°, 90°, 0°.

rather than planar like β_{LT}. Energy calculations are at present unable to deal with such solvent interactions, and so even when dramatic changes such as those of *c*-$(SPG)_2$ occur, the most that can be concluded is that both the β_{LT} and Ω_C conformations represent low energy forms.

The even more striking conformational behavior of the related cyclic hexapeptide, *cyclo*(-Pro-Gly-)$_3$, will be described by Dr. Deber later in this meeting.

Of the many cyclic polypeptides of more complex structure which have been investigated by pmr, let us briefly mention here the mushroom toxin antidote antamanide,[9,10,23-26] an all-L decapeptide having no element of symmetry:

```
   8   9   10  1   2
  Pro-Phe-Phe-Val-Pro
   |                 |
  Pro-Phe-Phe-Ala-Pro
   7   6   5   4   3
```

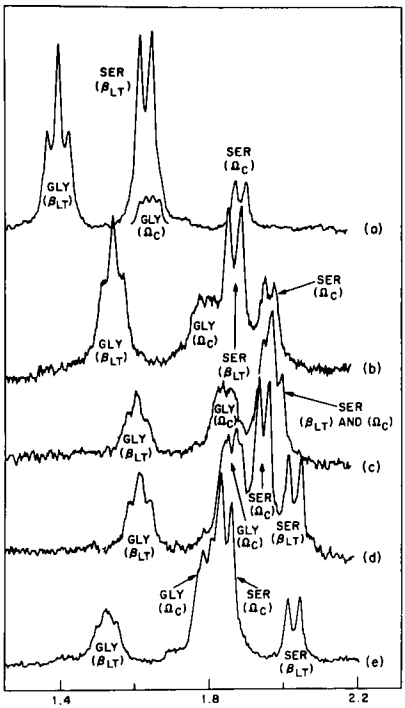

Figure 7: The 220 MHz NMR spectrum of the NH protons of *cyclo*(-Ser-Pro-Gly-Ser-Pro-Gly-); (a) in H_2O-CH_3COOH, 98:2 by vol.; (b), (c), and (d) in d_6-DMSO:H_2O-CH_3COOH (98:2); (e) in d_6DMSO. In (a) through (e) the mole fraction of d_6DMSO is 0.0, 0.5, 0.7, 0.8, and 1.0. Each spectrum is the result of 15-30 accumulated CAT scans (ref. 22).

Figure 8 shows the 220 MHz pmr spectrum of antamanide in CD_3CN at 34°. I will not discuss it in detail but show it as illustrative of the spectra of the more complex polypeptides which lack symmetry. The main parameters we need are the values of $J_{N\alpha}$, each assigned if possible to a specific residue in the sequence. An essential procedure is the association of the NH resonances (at 2-3 τ) with their corresponding α-protons (5-6 τ) and the association of these with the side-chain β-protons at higher field, and so on. This is done by *double resonance*. The irradiation of an α-CH multiplet causes the associated NH doublet to collapse to a singlet; the assignment may be confirmed by reversing the procedure and observing the resulting

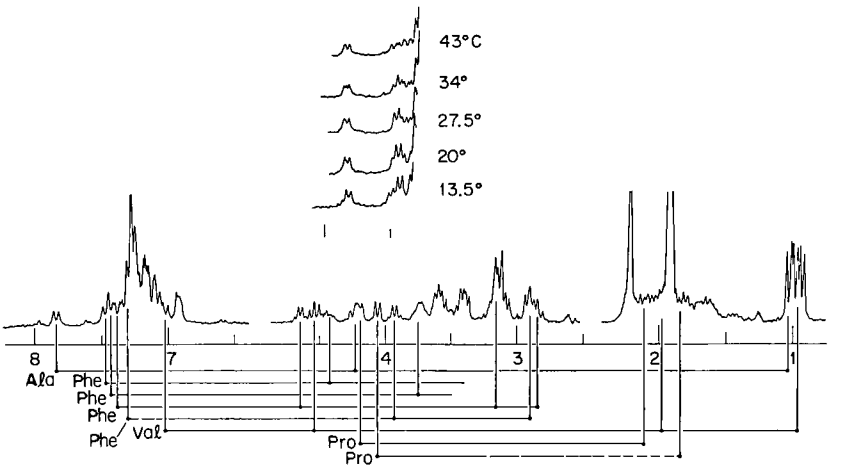

Figure 8: The 220 MHz proton spectrum of antamanide in CD_3CN at 34°. The lines below the spectrum connect NH, α- and β-protons shown by double resonance to be vicinally coupled. The inset spectra above show the temperature dependence of the NH portion of the spectrum, which in this solvent is relatively small.

perturbation of the α-region of the spectrum. This operation is then extended to the β, γ, etc. protons of the side-chain. The lines in Figure 8 connect multiplets corresponding to groups of spins demonstrated by this means to be (vicinally) coupled. From the form of the α-CH and sidechain multiplets the residues can be assigned by type but not specific sequence position. All the $J_{N\alpha}$ had relatively large values of 6.0 - 8.5 Hz. In CD_3CN and in CD_3CO_2H temperature coefficients were small for the chemical shifts of all six of the peptide NH doublets, two Phe resonances showing somewhat larger slopes than the other four residues. There are thus four strong intramolecular hydrogen bonds and two weaker ones. (An earlier study of

antamanide in $CDCl_3$[24] showed fast exchange rates for *all* NH resonances.) In strong hydrogen bond accepting solvents such as dioxane and N,N'-dimethylformamide, antamanide assumes a different conformation in which all peptide NH protons are exposed to solvent.

The proton studies of antamanide are hampered by the difficulty of having no entirely clear-cut test of whether the proline residues are *cis* or *trans* or both, although there does appear to be a correlation between the form of the pro α-CH multiplet and the state of the X-Pro bond (quartet for *trans* and "doublet" for *cis*). As we shall shortly see, however, cmr can provide very useful and important information on this point.

Antamanide is known to complex Na^+ quite strongly,[23,26] probably by folding to form a cavity in which several carbonyl groups can bond to the ion. It is found[10] that on adding NaSCN to a CD_3CN solution of antamanide, the peaks broaden as the mole ratio of Na^+ to polypeptide approaches 0.5 and then narrow again while assuming new positions corresponding to the Na^+ complex. There is no actual "doubling" of the spectrum at any point. Analysis of this behavior shows that the barrier in the process

$$\text{Ant}\cdot Na^+ + \text{Ant} \rightleftarrows \text{Ant}\cdot Na^+$$

is no greater than *ca.* 15 kcal. and that therefore no significant alterations in X-Pro peptide bond conformations occur on complexation. Again, cmr, which we now discuss, provides important confirmatory information.

Carbon-13 NMR

As is well known, the inherent observing sensitivity of C-13 is low owing to a natural isotopic abundance of 1.1% and a gyromagnetic ratio only about one-fourth that of the proton. This disadvantage has been very successfully overcome in the last 3-4 years by multiple scan techniques and, still more recently, by Fourier transform spectroscopy. Further increase in signal-to-noise ratio is accomplished by abolishment of ^{13}C-^1H J couplings using a noise-modulated proton decoupling field; this has the further advantage of an accompanying nuclear Overhauser enhancement of as much as 3-fold. As we have seen, one is repaid for all this extra trouble by a range of chemical shifts *ca.* 30-fold larger than for protons, with corresponding increase in discrimination of structural and conformational features.

In a general way, the chemical shift positions of carbon resonances in polypeptide spectra (commonly, as here,

ppm FROM $^{13}CS_2$

expressed with respect to $^{13}CS_2$ as zero) are fairly well understood,[2-10] but there are marked perturbations arising from secondary influences, probably chiefly conformational, of which only a glimmer of understanding can be claimed at present. It is fortunate that such perturbations occur, for if a C-13 spectrum were only a summation of the resonances of the individual amino acid residues it would not be very informative.

In Figure 9 are shown the C-13 spectra of the precursor peptides of oxytocin[7] from Pro-Leu-Gly-NH_2 (a) through the nonapeptide (g) and finally closing the ring (h); [D-Pro7]-oxytocin is shown as (i). I will comment only in a general way on these spectra, my purpose in showing them being to indicate the general appearance of C-13 spectra of polypeptides. In the least shielded region, between 10 and 30 ppm, are the carbonyl resonances of the peptide groups and the Asn, Gln, and Gly-NH_2 carboxamide groups. Aromatic resonances of Tyr and the *S*-benzyl, *O*-benzyl, and carbobenzoxy blocking groups (and the carbobenzoxy carbonyl) appear between 35 and 74 ppm. The α-carbons appear between 130 and 150 ppm, Gly being the most shielded and Pro the least. Benzylic methylene carbons of Tyr-*O*-benzyl, of carbobenzoxy, and of Cys-*S*-benzyl appear just below and

just above this range of chemical shifts, respectively. The large multiplet at *ca.* 150 ppm is that of the d_6-DMSO solvent; the deuterons are not decoupled by the proton decoupler, and give a 1:3:6:7:6:3:1 septet with *ca.* 20 Hz spacing; in the oxytocins, this masks the peaks of Asnβ, Leuβ, $Cys_1\beta$, and $Cys_6\beta$. The Pro δ-carbons appear at *ca.* 146 ppm in all spectra. Between 152 and *ca.* 167 ppm the β-carbons appear and beyond this up to 182 ppm are the Pro γ-carbons and those still further out on the Leu and Ile sidechains. The latter can be unambiguously identified by use of the empirically derived rules for carbon chemical shifts in alkanes.[27-30]

Careful analysis of these spectra permits detailed assignments of all the carbon peaks. These are shown in schematic form in Figures 10, 11 and 12; dotted lines connect peaks for corresponding carbons in different spectra. Little deviation occurs in the open-chain polypeptide spectra beyond what can be readily attributed to end-groups. But when the nonapeptide is closed to yield oxytocin, there are alterations of many resonance positions, particularly of the α-carbons. The assignment of the Cys peaks in oxytocin is based on deuterium labelling, which causes the labelled carbon resonance to broaden and virtually disappear. Some of these assignments await further confirmation.

Extensive further study and interpretation will be required before the power of cmr in such investigations is fully realized. The most immediately useful result of our present studies is the determination of the *cis*- or *trans* state of the X-Pro bond. As we have seen, pmr is ambiguous for this purpose; it clearly reveals both forms when present but does not identify them. Cmr is more positive in this regard, although not always entirely unambiguous. Figure 13 shows schematic cmr spectra of proline and a number of simple proline derivatives and peptides, including poly-L-proline I and II. The assignments are based on the observations of the polyprolines and of a number of simple amides[31] and appear to be secure. The heights of the lines indicate approximately the apparent proportions of *cis* and *trans* conformers. One can see that whereas the α, δ and (particularly) carbonyl resonances do not show a fixed pattern of relative chemical shifts for *cis* and *trans*, the pattern of the β and γ carbons is, with only minor perturbations, entirely consistent. These resonances show the "back-to-back" intensity pattern to be expected if the β- and γ-carbons experience the same relative environmental influences when *syn* or *anti* to the carbonyl group. (The

origin of these chemical shift differences is not at present clear; electric field effects have been suggested as a possible cause.[32]) A similar pattern appears in the α and δ resonances for some compounds but for others it is reversed.

Application of these criteria to larger molecules will clearly be significant. Examples are illustrated in Figure 14. For example, the Pro β- and γ-carbon resonances in gramicidin A (data of Gibbons *et al.*[3]) are unmistakably in the *trans* positions, confirming the structure deduced for this molecule.[3,15,33] The eight line β- and γ-carbon pattern of antamanide[9] shows a grouping into two *cis* and two *trans* X-Pro bonds, resolving the ambiguity of the proton spectrum. At the same time, the close spacing of the lines in each group confirms the near two-fold symmetry of the proposed conformation in acetonitrile.[9] (There is an extra line, assigned to Val β, in the lowest field group.) Of equal significance is the fact that this pattern is retained with little change in the spectrum of the Na^+ complex. This is consistent with the conclusion from proton studies, discussed earlier, that no X-Pro bond conformations are altered when the complex is formed. The conformation deduced from pmr and cmr[9,10] for antamanide is shown in Figure 15, and for the Na^+ complex in Figure 16.

In Figure 14 are also shown the assigned resonances for Pro α, β, γ and δ carbons in the oxytocin precursor peptides, extracted from Figures 10 and 11. When Cys is added to Pro-Leu-Gly-NH_2, *cis* and *trans* X-Pro conformers become possible and are observed. But when Asn is added, the *cis* conformer is suppressed. The last finding agrees with the findings of Smith *et al.*, reported in this meeting. The Pro carbons maintain a consistent *trans* pattern in the open-chain peptides and upon closing the ring.

CHEMISTRY AND BIOLOGY OF PEPTIDES

A CARBON-13 NUCLEAR MAGNETIC RESONANCE STUDY OF NEUROHYPOPHYSEAL HORMONES AND RELATED OLIGOPEPTIDES

Ian C. P. Smith, Roxanne Deslauriers. Division of Biological Sciences, National Research Council of Canada, Ottawa, Canada K1A 0R6

Roderich Walter. Department of Physiology, Mount Sinai School of Medicine, City University of New York, New York, New York 10029

PROTON MAGNETIC RESONANCE (PMR) has been useful for deriving conformational information and constructing molecular models for oxytocin[1-3] and lysine-vasopressin[4-8] in solution. However, the twenty-fold greater range of chemical shifts for carbon-13 implies that much better resolution of individual resonances could be obtained. The chemical shifts of ^{13}C have been shown to be very sensitive to conformational effects in small molecules.[9,10] Coupling constants between carbon and hydrogen,[11] and carbon and phosphorus,[12,13] have also been shown to be conformation-dependent. The relaxation times, T_1, of individual carbon atoms are indicative of mobilities of different regions of a molecule.[14] The value of ^{13}C magnetic resonance (CMR) has not yet been conclusively demonstrated in conformational studies on peptides other than valinomycin.[15]

We have obtained the CMR spectra of oxytocin (Figure 1), lysine-vasopressin (LVP), 1-deamino lysine-vasopressin (DLVP) (Figure 1), and arginine-vasopressin (AVP) in deuterated dimethylsulfoxide (DMSO-d_6) and deuterium oxide (D_2O). As expected, a high degree of resolution was obtained, with separate resonances being observed for almost every carbon atom in the molecule. However, due to the large number of similar resonances, and to slight changes in chemical shifts associated with neighbour effects, it was not possible to

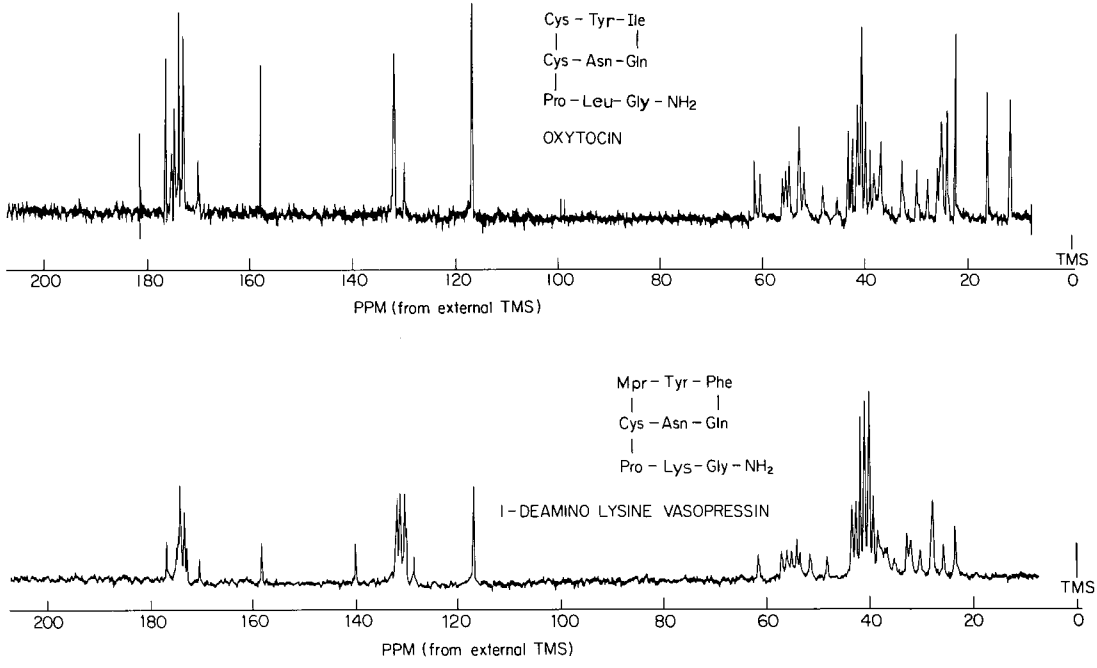

Figure 1: Fourier transformed CMR (25.16 MHz, Varian XL-100-15) spectra of oxytocin (40 mg/0.2 ml, 84,000 accumulations) and 1-deamino lysine-vasopressin (40 mg/0.2 ml, 112,000 accumulations) in DMSO-d_6 at 37°C. Carbon-hydrogen spin couplings have been removed from the spectra by broad band (noise) decoupling of hydrogen. The sweep width is 5000 Hz, and data (4096 points) were accumulated with an aquisition time of 0.4 seconds. The sharp line at 182 ppm in the spectrum of oxytocin is an instrument artifact and should be disregarded. The regions at 40 ppm contain seven line multiplets from the CD_3 groups of DMSO-d_6. Mpr = β-mercaptoproprionic acid.

assign all the resonances by reference merely to data for the constituent amino acids or model dipeptides. We therefore obtained the CMR spectra of the constituent peptides of oxytocin, from the carboxamido-terminal tripeptide to the partially protected, uncyclized nonapeptide. Thus we were able to follow the influences of specific neighbouring groups, and of cyclizing the nonapeptide. Detailed assignments of the various spectra[16] cannot be presented here; they are available on request and will be published elsewhere. We discuss herein some of the observed effects and their significance.

Discussion

In the CMR spectra of the peptides, Z-Pro-Leu-Gly-OEt and Z-Pro-Leu-Gly-NH_2, two resonances were observed for the α, β, and δ carbons of Pro (the γ resonance is obscured partly by the δ of Leu, and doubling cannot be easily detected). We attribute this to the presence of both *cis* and *trans* isomers of the carbobenzoxylated Pro in these tripeptides. Elongation of the deprotected tripeptide to the protected tetrapeptide, Z-Cys(Bzl)-Pro-Leu-Gly-NH_2, results in loss of one set of Pro resonances, as is the case with all higher-membered peptide intermediates studied as well as with the hormones. This indicates a strong preference for the *trans* conformation of Pro. PMR (220 MHz) of the protected tetrapeptide confirms the *absence* of the *cis* conformer,[17] and the *presence* of the *cis* conformer in the tripeptide.[18]

In successive additions of protected N-terminal residues to the oligopeptides, the principal changes in ^{13}C chemical shift were observed in the penultimate residue. For example, on adding Z-Gln to Z-Asn-Cys(Bzl)-Pro-Leu-Gly-NH_2, the only observed changes in chemical shift are for Asn (α, -2.0; β, -0.3; carbonyl, +0.2 ppm). The one exception to this rule is Pro, whose α resonance is insensitive to *N*-peptide formation, possibly because it is a secondary amine to begin with. Further studies of proline-containing peptides are required in order to test the generality of this observation. The protecting groups (Z, Bzl, *etc.*) affect mainly the resonances of the protected amino acids.

The deprotected oligopeptides were studied in both D_2O and DMSO-d_6. This served as a measure of direct (non-conformational) solvent effects. In general the chemical shifts in DMSO-d_6 relative to those in D_2O were: α to higher field; β to higher or lower, depending on the amino acid; CH_3 to lower field; carbonyl 2.8 ppm to higher field.

This demonstrates that caution must be taken in interpreting data taken in non-aqueous solvents, and in comparing them with data taken in water.

Cyclization of the protected nonapeptide to form oxytocin gives rise to numerous changes in the CMR spectrum. The major changes are in the α and carbonyl carbon resonances of the amino acids of the cyclized portion. This in itself suggests that the effects have a conformational origin, as do temperature studies (*vide infra*). In general the α resonances move to lower field on cyclization. Formation of hydrogen bonds, as have been proposed[3] between the peptide NH of Asn and the carbonyl of Tyr, and between the side peptide NH of Gly and the carbonyl of Cys-6, should result in downfield shifts of the carbonyl resonances involved.[19,20] To estimate the magnitude of the downfield shift, we studied the system guanosine-cytidine in DMSO-d_6. PMR has shown that these compounds form dimers by hydrogen bonding.[21] Under optimal conditions for hydrogen bonding, we observed low field shifts in the hydrogen-bonded carbonyls of 0.27 ppm (cytidine) and 0.66 ppm (guanosine). Displacements of this magnitude, in addition to displacements caused by other effects of cyclization, makes unambiguous assignment of the carbonyl resonances difficult. In an attempt to resolve this problem, we studied a series of closely related hormones.

Figure 1 compares the CMR spectra of oxytocin and DLVP, which differ in three positions. Expected differences are the two Ile methyl resonances at 12.8 and 17.1 ppm in the spectrum of oxytocin, the five aromatic Phe resonances centered around 130 ppm in the spectrum of DLVP and the cysteine in position 1, in which the NH_2 has been replaced by H. There are of course greater differences between the spectra of oxytocin and the vasopressins, than there are between the spectra of the various vasopressins themselves. In particular, the α resonances of Asn and Cys-6 differ by +1.2 and -0.4 ppm, respectively, on comparing oxytocin and DLVP. Most of the other spectral differences can now be interpreted, although there remain uncertainties regarding our assignments in the carbonyl region.

Elevation of the temperature of oxytocin solutions in DMSO-d_6 results in changes in only a few resonances. In particular, the β resonance of Gln and the α resonance of Ile move towards the values found for the protected nonapeptide of oxytocin. This suggests that both the Gln β and Ile α resonances are conformationally sensitive.

Comparison of the CMR spectra of LVP and AVP reveals very few differences in the chemical shifts of the amino acids held in common.

Differences in the spectra of the various hormones in D_2O or DMSO-d_6 parallel for the most part the solvent-induced changes in the uncyclized peptides. We have therefore no evidence for any dramatic conformational differences for the hormones in these two solvents; however, this may be a limitation in the sensitivity of ^{13}C chemical shifts to small conformational changes in peptides.

Conclusion

The CMR spectra of the nonapeptide hormones manifest the expected high resolution. By studying the constituent oligopeptides almost all resonances can be assigned. For some resonances a study of slightly modified hormones is required for a complete assignment. Carbonyl and α-carbon resonances appear to be conformationally sensitive, but models for the observed behaviour cannot be constructed until further information is available on conformational influences on ^{13}C chemical shifts. Using the chemical shifts arbitrarily, one can say that the conformations of LVP, DLVP and AVP are very similar. It appears that the conformations of the hormones are similar in DMSO-d_6 and D_2O.

Although the conformational effects on ^{13}C chemical shifts are relatively small (1-2 ppm), they should be useful for determining the structures of such hormones in solution. Considerable difficulty may be encountered with larger peptides, however, and enrichment of specific amino acids in ^{13}C may be necessary. The measurement of relaxation times in such systems should also prove fruitful, especially in those with enriched amino acids where the time required for the experiment becomes reasonable. Couplings between carbon and hydrogen also provide hope for future conformational insight via CMR.

CHEMISTRY AND BIOLOGY OF PEPTIDES

ENERGY REFINEMENT OF THE NMR STRUCTURE OF OXYTOCIN AND ITS CYCLIC MOIETY

David Kotelchuck. Department of Chemistry, Cornell University, Ithaca, N.Y. 14850 and Department of Physiology, Mt. Sinai School of Medicine of the City University of New York, New York, N.Y. 10029.

Harold Scheraga. Department of Chemistry, Cornell University, Ithaca, N.Y. 14850.

Roderich Walter. Department of Physiology, Mt. Sinai School of Medicine of the City University of New York, New York, N.Y. 10029.

IT HAS PREVIOUSLY BEEN SHOWN[1,2] that the combined use of conformational energy calculations and NMR measurements can resolve ambiguities present in both techniques, and thereby provide structural information about polypeptides in solution. The main ambiguity in the computational method [which was encountered in earlier calculations on oxytocin[3]] is the existence of many local minima in the energy surface of the peptide; in the NMR method a major ambiguity presently resides in the inability to obtain a unique structure from the limited available experimental data. However, if a possible structure is proposed for a polypeptide on the basis of the NMR data, its energy and that of its variants can be examined to assess the possible validity of the proposed structure. This was done for the proposed NMR structure of oxytocin,[4] which consists of two β-turns, involving the sequences Tyr-Ile-Gln-Asn in the six-residue ring and Cys-Pro-Leu-Gly-NH_2 in the acyclic tail (Figure 1). The resulting conformation is valid only if the proposed structure is close to the correct one, and

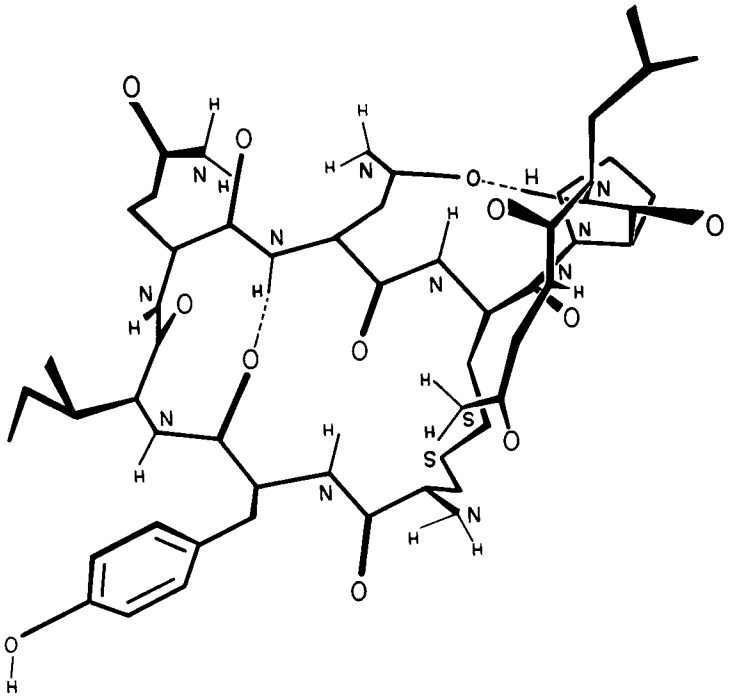

Figure 1: Proposed conformation of oxytocin in DMSO.[4]

if reliable geometry parameters and energy functions are used in the computations.

The isolated six-residue ring of oxytocin, the cyclic moiety, was examined first. Initial dihedral angles were measured from space-filling models based on the proposed structure.[4] Twenty related conformations were generated by allowing the dihedral angles to vary randomly up to ±30° from these measured values. After minimization, none of the 20 conformations had two backbone hydrogen bonds in the ring, and only four had a single hydrogen bond. Furthermore, the average final energy of the four conformations with a single hydrogen bond was the same as that for conformations without a hydrogen bond. To assure that no low-energy hydrogen bonded states existed that were inaccessible from the above conformations because of the existence of local minima, an exhaustive examination of conformation space was conducted looking for structures with hydrogen bonds. Out of 1134 ring conformations

examined, only 16 had geometries with two hydrogen bonds, of which four were selected for further study (Table I).

Table I

Selected Conformations of the Tyr-Ile-Gln-Asn Sequence with Two Hydrogen Bonds

Conformation Number	*Tyr*		*Ile*		*Gln*		*Asn*	
	ϕ	ψ	ϕ	ψ	ϕ	ψ	ϕ	ψ
1	-140	170	-50	-40	-120	30	-140	140
2	-170	170	-50	120	120	-30	-170	140
3	-140	170	-70	-20	-90	0	-170	110
4	-140	170	-70	120	90	0	-140	110

Energy minimization of these four broke all initial hydrogen bonds, except for one weak hydrogen bond in the Conformation 3 of Table I. The final energies of the four conformations were the same or greater than the average of the 20 conformations examined above. When the acyclic tripeptide tail was added to each of the four conformations, forming a complete oxytocin molecule, all but one of the initial ring hydrogen bonds broke during energy minimization. We conclude that oxytocin conformations with two hydrogen bonds in the ring do not form, while conformations with a single hydrogen bond in the ring can form, but have the same energies as those without such bonds. This result is consistent with the one hydrogen bond proposed for the ring of oxytocin,[4] but in disagreement with the two hydrogen bonds proposed for the ring of deamino-oxytocin.[5] The discrepancy could be due to differences in solvation between DMSO and water--the measurements were made in DMSO and the calculations for water as a solvent. (Calculations ruled out any direct effect of the terminal amino group on hydrogen bonding in the ring.)

As regards the tail of oxytocin, in three of the four conformations considered the proposed hydrogen bond between the Gly peptide NH and the Cys-6 C=O remained intact after minimization. The hydrogen bond between the Leu peptide NH and the Asn side chain C=O, which was proposed to form

when the tail is over the ring, did not form in any of these cases. However, a study of the dependence of the energy on the angle ψ of the Cys-6 residue shows an allowed conformation with the tail over the ring, as in the proposed structure,[4] as well as one with the tail away from the ring. The Tyr side chain also appears to have two allowed orientations--one folded over the ring, and the other stretched away from it.

In summary, the structures calculated for oxytocin are not inconsistent with the proposed NMR structure, making allowance for the use of water as a solvent in the calculations and DMSO in the NMR studies. However, the range of allowed conformations, all of roughly equal energy, suggests that there may be considerable flexibility in the oxytocin molecule. Fuller details are given in reference 6.

CHEMISTRY AND BIOLOGY OF PEPTIDES

PROTON AND ^{13}C NMR STUDIES OF CONFORMATIONS OF *CYCLO* (-PRO-GLY-)$_3$

C. M. Deber, E. R. Blout. Department of Biological Chemistry, Harvard Medical School, Boston, Massachusetts 02115

D. A. Torchia, D. E. Dorman, F. A. Bovey.* Bell Laboratories, Murray Hill, New Jersey 07974

IN CONTRAST TO SEVERAL CYCLIC hexapeptides whose solution conformations have been studied,[1-4] the presence in *cyclo* (-Pro-Gly-Pro-Gly-Pro-Gly-) (abbreviated *c*-(PG)$_3$) of three L-prolyl residues in alternating positions precludes the formation of intramolecularly hydrogen-bonded antiparallel β-type structures. Instead, this peptide may have a conformation with a 3-fold symmetry and in this way resembles *cyclo*(tri-L-prolyl).[5] In *c*-(PG)$_3$, however, glycyl residues intervene between each prolyl residue, resulting in a situation where the three Pro-Gly peptide bonds must be *trans*, while the three Gly-Pro peptide bonds may be either *cis* or *trans*.[6,7]

220 MHz proton NMR spectra have shown[8] that *c*-(PG)$_3$ dissolved in methylene chloride-d$_2$ (CD_2Cl_2) exists predominantly in a C_3-symmetric conformation, as judged by the magnetic equivalency of the three Pro-Gly units. The Gly NH region of the spectrum, shown in Figure 1a, consists of a single resonance indicated as S, coupled to the Gly $C_\alpha H_2$ protons with $J_{N\alpha}$ of 2.5 and 4.0 Hz. This information, taken in conjunction with symmetry requirements and other indications from molecular models, suggests that the backbone

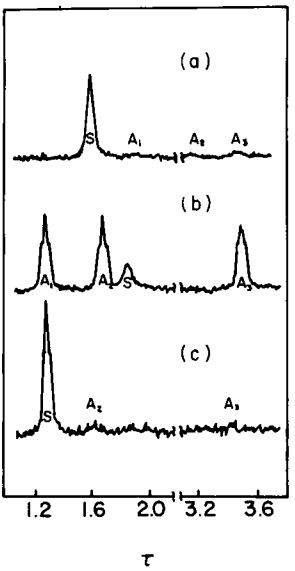

Figure 1: Peptide NH region of the proton NMR spectra of *cyclo*(-Pro-Gly-)$_3$ at 220 MHz. Solvents: (a) CD_2Cl_2; (b) DMSO-d_6; (c) DMSO-d_6 + NaSCN. In (c), the molar ratio NaSCN/*c*-(PG)$_3$ ≈ 7. Chemical shifts (τ scale) given in ppm downfield from TMS.

conformation of *c*-(PG)$_3$ in methylene chloride consists of three *cis* Gly-Pro peptide bonds, three *cis*' Pro C_α-C=O bonds, and three sets of Gly (ϕ,ψ) angles of *ca.* (0°,0°).

The striking sensitivity of *c*-(PG)$_3$ conformations to solvent is seen in Figure 1b. Upon changing from CD_2Cl_2 (1a) to dimethylsulfoxide-d_6 (DMSO-d_6), the three Gly NH protons now appear as three resonances of equal area, demonstrating that the predominant structure is asymmetric in DMSO-d_6 solution. Mixed CD_2Cl_2- DMSO-d_6 solvent studies demonstrated[8] a dynamic equilibrium between the two *c*-(PG)$_3$ conformers, and minor populations of each conformer can be seen in both pure solvents (Figures 1a and 1b).

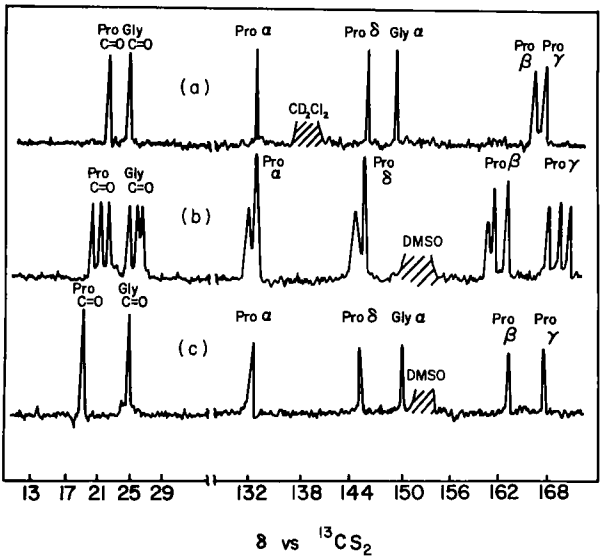

Figure 2: ^{13}C NMR spectra of *cyclo*(-Pro-Gly-)$_3$ at 25.2 MHz. Solvents: (a) CD_2Cl_2; (b) DMSO-d_6; (c) DMSO-d_6 + NaSCN. In (c), the molar ratio NaSCN/*c*-(PG)$_3$ ≈ 7. The Gly C_α resonances are obscured by solvent in (b). A resonance for the SCN^- carbon atom appeared in (c) near 62 ppm. Chemical shifts given in ppm upfield from $^{13}CS_2$. ^{13}C spectra have been redrawn from the original spectra for clarity.

Addition of sodium thiocyanate to DMSO-d_6 solutions in increasing molar amounts converts the asymmetric structure to a *new C$_3$-symmetric conformer*, as shown in Figure 1c, where ~90% of *c*-(PG)$_3$ molecules are C3-symmetric when the molar ratio NaSCN/*c*-(PG)$_3$ ≈ 7. This transformation may be attributed to the formation of a stable cyclic peptide-sodium thiocyanate complex, and analysis of its complete NMR spectrum suggests[8] a backbone conformation containing three *trans*' Pro C_α-C=O bonds and three *trans* Gly-Pro peptide bonds. Other alkali metal cations also convert *c*-(PG)$_3$ to C3-symmetric conformers in DMSO-d_6. Under

conditions similar to those used with NaSCN, the following percentages of complexed cyclic peptide were observed: K^+, 75%; $Li^+ = Rb^+$, 50%; and Cs^+, 25%. Models suggest that either the three Gly carbonyl groups and/or the three Pro carbonyl groups in the all *trans'*/*trans* c-$(PG)_3$ conformer are well-oriented to bind metal cations, but the overall stoichiometry of the complex is presently undetermined. A 2:1 peptide-cation "sandwich" complex, where the ion is bound to six peptide carbonyl oxygens between two cyclic peptide molecules, seems possible.

In addition to the proton spectra of c-$(PG)_3$, it was of interest to examine the corresponding ^{13}C NMR spectra to ascertain if these various conformational transitions could be effectively monitored with this method; if further conformational information would become available; and to determine if chemical shift differences between the spectra could be related to conformational features with confidence. Figure 2a, b, c shows the complete ^{13}C spectra of c-$(PG)_3$ under the conditions corresponding to Figure 1a, b, c. Both the Gly and Pro peptide carbonyl carbon atoms may be seen in 2a, whereas in proton NMR, proline residues give no resonance in the peptide NH region. (Assignments of carbonyl resonances were made by synthesizing c-$(PG)_3$ ~60% enriched with ^{13}C in one Gly carbonyl of the linear hexapeptide precursor Gly-Pro-Gly-Pro-Gly-Pro-nitrophenyl ester hydrochloride, which gives, after cyclization, c-$(PG)_3$ with each Gly carbonyl enriched ~20%.)

The asymmetry induced by dissolving c-$(PG)_3$ in DMSO-d_6 is reflected clearly in the carbonyl region of ^{13}C spectrum 2b, where three carbonyl resonances are present for *both* the three non-equivalent Gly carbonyl carbons and the non-equivalent Pro carbonyls. Furthermore, when sodium thiocyanate is added to the DMSO-d_6 solution of c-$(PG)_3$ in about 7-molar excess, spectrum 2-c demonstrates the transformation back to three-fold symmetry, as observed in proton NMR. The downfield movement of the Pro carbonyl carbon while the Gly remains constant (compare 2a versus 2c) suggests involvement of the Pro carbonyls with salt. A similar effect has been recently observed in valinomycin-K^+ complexation.[9]

The upfield portions of spectra 2a and c also indicate the C_3-symmetry present in contrast to the asymmetry evident in 2b. Assignments of resonances are made by comparison with a number of proline ^{13}C spectra.[10] Chemical shifts are generally in regions "normally" observed for most proline peptides,[10] with the notable exception of the Pro C_β-carbon resonance in 2a, which falls about 4 ppm upfield from the position expected for a proline residue involved

in a *cis* peptide bond. Since *c*-$(PG)_3$ dissolved in CD_2Cl_2 is a proline peptide proposed to contain *cis*' Pro C_α-C=O bonds, the upfield shift may be diagnostic for this conformational feature which, to date, has not been directly observed experimentally.

CARBON-13 NUCLEAR MAGNETIC RESONANCE OF SOME PENTAPEPTIDES

Frank R. N. Gurd, Philip Keim, V. G. Glushko, P. J. Lawson, R. C. Marshall, A. M. Nigen, and R. A. Vigna.*
Department of Chemistry, Indiana University, Bloomington, Indiana

THE FOLLOWING PROGRESS REPORT deals with ^{13}C NMR studies on a series of pentapeptides. The peptides were constructed as models for comparison with observations on proteins. A previous report has indicated that the central residue of a pentapeptide is fairly well isolated from terminal-residue effects, whereas the central residue of a tripeptide may not be so well isolated.[1] The peptides reported here all have glycyl residues in the first, second, fourth and fifth positions with some particular L-amino acid represented in the third position. The solid phase technique was used for synthesis, with *t*-Boc-diglycine employed to reduce the number of steps. Cleavage from resin and deblocking were done in trifluoracetic acid-HBr. Several standard variants were used and will be presented in full publications. Purity was checked by amino acid analysis, thin-layer chromatography and by the ^{13}C NMR itself.

Samples were prepared of the order of 1*M* solutions in water with an internal dioxane standard. The pH was adjusted with 5*N* NaOH or 6*N* HCl and measured at 25°. NMR observations of the ^{13}C nucleus at natural abundance were made at 15.1 MHz under ^{1}H decoupling conditions. The pulsed Fourier transform mode was used. Resolution was taken to about 0.12 ppm. Chemical shifts were expressed as parts per million upfield from CS_2,[1] with dioxane taken as 126.3 ppm on this scale. Measurements were made at 26 to 28°. The pulse-delay sequence (Inversion Recovery Method) for measurements of the spin-lattice relaxation time, T_1, has been described.[2-4]

*Present Address: Department of Chemistry, University of Queensland, St. Lucia, Qld. 4067, Australia

The Broader Objective

Before showing the types of results obtained, it is useful to have in mind the objectives in protein chemistry that this study is intended to serve. These are to establish chemical shift positions to be expected for the carbon nuclei in amino acid residues in the interior and at the ends of polypeptide sequences, to determine the effects of changes in protonation state at nearby sites, and to gain a picture of the T_1 values observed in a short, free segment of peptide chain. In the long term the most important applications to protein studies will probably come from enrichment in which the skill of the peptide synthetic chemist will be decisive. Carboxymethylation with enriched bromoacetate has recently shown that a single enriched locus can be observed by ^{13}C NMR with such proteins as myoglobin and ribonuclease A.[5]

Chemical Shifts

The main point to note about the chemical shift results is that a given carbon nucleus in a central residue of a pentapeptide does seem to fall in a position matching its attribution in a denatured protein spectrum.[4] Of nearly equal importance is the strong pH dependence of the shifts of nuclei close to sites of variable protonation. Some examples of magnitude and direction of changes in chemical shift with pH, and of the corresponding pK values, are shown in Table I. Such effects may prove useful in proteins for observing the influence of an ionizing group on a near neighbor, especially if the latter is enriched with respect to ^{13}C.

Relaxation Studies

In addition to a number of spectral measurements at various pH values to obtain the information outlined above, relaxation measurements have been made to obtain T_1 values, often at two pH values for each pentapeptide. The technique is like other perturbation techniques in which the time course of the reestablishment of equilibrium is followed. For molecules in the size range under consideration the ^{13}C-^{1}H dipolar relaxation mechanism is dominant for carbons attached directly to protons. The spin-lattice relaxation time, T_1, describes this exponential process.[3,6] For molecules in this size class it is also characteristic that

Table I

Chemical Shifts and pK Values for Some Central Amino Acids in Gly-Gly-X-Gly-Gly Pentapeptides

All chemical shifts are expressed as ppm upfield of CS_2. Titrations were performed on *ca.* 1*M* peptide solutions and pK values were obtained by computer fitting to a simple Henderson-Hasselbalch curve

	Tyrosine			*Histidine*

those protonated carbon nuclei undergoing the most rapid tumbling motion will generally show the longest values of T_1.

Figure 1 is a diagram showing T_1 values in milliseconds for the pentapeptides containing the following central residues: (A) alanine, (B) lysine and (C) tyrosine. The T_1 values shown are the actually measured values multiplied by the number of directly attached hydrogens for direct comparison (*i.e.* NT_1). In each case the peptide backbone is represented only by the α-carbons. All side chain carbon values are shown, including C^{γ} and C^{ζ} of tyrosine which are not directly protonated and have much longer values of T_1 that are not interpretable in the same terms.

For each of the three cases, and for the others that we have studied as well, the α-carbon NT_1 values are greater at the ends of the peptide chains than in the center, with intermediate values for C^{α} of residues 2 and 4. The result for C^{β} of the alanine peptide presumably reflects contribution from the spinning of the methyl group around the C^{α}-C^{β} axis. The side chain carbon nuclei of the lysine residue show a gradation in NT_1 that fits qualitatively with the idea that rotational motion is freer the farther out the chain that one considers. This idea parallels the argument in explanation of the longer values for the C^{α} nuclei of

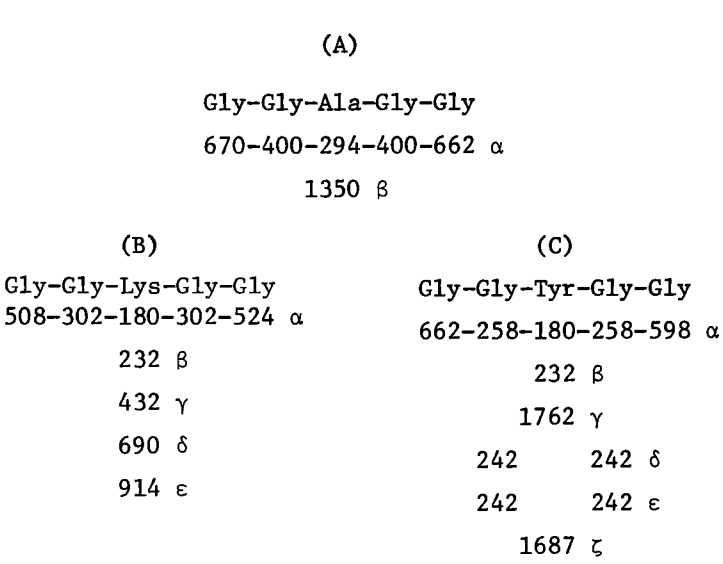

Figure 1: Schematic representation of NT_1 values for the pentapeptides in neutral solution: A, glycylglycyl-L-alanylglycylglycine; B, glycylglycyl-L-lysylglycylglycine; C, glycylglycyl-L-tyrosylglycylglycine. The values for α-carbons are shown horizontally.

the terminal glycine residues compared to the more central residues. These interpretations follow those of Allerhand and his coworkers in similar situations.[3,6] The observations on the tyrosine peptide are interesting in that NT_1 is comparable for all the hydrogen-bearing carbons of the side chain. The simplest explanation is that here motion is dominated by components in which the side chain revolves about its axis of attachment to the peptide chain, again a type of behavior observed in a somewhat similar system by Allerhand's group.[7] Information of this type, treated with suitable caution, should be of value in interpreting observations on proteins.[8]

STUDIES ON THE CYCLIZATION TENDENCY OF PEPTIDES

M. Rothe, R. Theysohn, D. Mühlhausen, F. Eisenbeiß, and W. Schindler. Organisch-Chemisches Institut, Universität Mainz, Germany

CYCLO-PEPTIDES CAN BE synthesized according to two basic approaches: (1) by ring closure of activated linear peptides at high dilution, and (2) by insertion reactions into preformed rings, *e.g.* by aminoacyl incorporation into diketopiperazines.

As to the first approach, the phosphite method has proved to be particularly useful in our group.[1] In the meantime we succeeded in preparing biological active *cyclo*-peptides, *e.g.* gramicidin S and its analogues, fungisporin (M. Zamani) and valinomycin oligomers (W. Kreiss). Unprotected peptides react with a chlorophosphite or pyrophosphite to give a mixed anhydride which cyclizes spontaneously. The main advantages of this method are the experimental simplicity and the high yields up to 80%.

We also used this method as well as the active ester cyclization in our investigations on the formation tendency of *cyclo*-peptides. In particular, the influence of the chain length of the peptides as well as the peptide concentration, and the nature and configuration of the amino acids have been studied.

As is well known, the cyclization tendency is particularly high in the case of the 6-membered *cyclo*-dipeptides. On the contrary, 7-membered peptide rings containing one β-amino acid are not formed spontaneously. The product obtained by Sekiguchi[2] from β-alanyl-glycine using the azide method has been found not to be the 7-membered *cyclo*-dipeptide, as envisaged, but the 14-membered *cyclo*-tetrapeptide (mp<350°). Its structure was determined by

incorporation of two β-alanine residues into glycine diketopiperazine. Using the phosphite method, the much more soluble 7-membered ring (mp 171-172°) could be isolated by gel filtration. In more concentrated solutions (0.01 *M*), the 14- and 21-membered dimers and trimers are formed in yields of 28% and 4.5%, respectively (monomer: 28%).

If glycine is replaced by proline which contains a rigid N-C_α bond, the cyclization tendency will be increased considerably. Even at the relatively high concentration of 0.01 *M*, 41% of the highly strained *cyclo*(-Pro-βAla-) was obtained without any formation of higher ring homologues. Model studies show that both peptide bonds must deviate considerably from planarity (by about 30% each).

It is well known that 9-membered *cyclo*-tripeptides can only be obtained in exceptional cases from linear peptides containing tertiary peptide bonds. As the first example, we could synthesize *cyclo*-triprolyl[3] in yields of more than 80%. Later on, *cyclo*-trisarcosyl has been prepared by Dale.[4] In order to obtain a series of *cyclo*-tripeptides in which proline is successively replaced by sarcosine, we now have synthesized *cyclo*(-Sar-Pro-Pro-) and *cyclo*(-Sar-Sar-Pro-).

During the cyclization of the tripeptides containing sarcosine, a series of oligomeric ring peptides is formed, even at high dilution, in addition to the *cyclo*-tripeptides (Figure 1). In more concentrated solution, the corresponding 18-, 27-, and 36-membered cyclic hexa-, nona-, and dodecapeptides could readily be isolated by gel chromatography. The amount of the higher homologues increases with increasing flexibility of the peptide chain, *i.e.* with decreasing content of the rigid proline rings. Accordingly, *cyclo*-trisarcosyl has been formed only in small amounts in addition to cyclic hexa-, nona-, and dodecasarcosyl. On the contrary, the introduction of 1 or 2 proline residues leads to *cyclo*-tripeptides, even in considerably higher concentrations (0.01 *M*), along with the higher rings up to dodecapeptides.

As side products, the corresponding diketopiperazines are formed in each case by peptide cleavage, especially at higher temperatures. This is pronounced in the cyclization of trisarcosine with predominant formation of *cyclo*-disarcosyl. The prevailing formation of *cyclo*(-Pro-Sar-) from Pro-Sar-Sar active esters shows that the cleavage is effected essentially from the amino end (cf. [5]).

Table I shows that the formation of cyclic tripeptides increases very much with increasing number of proline residues, even in relatively concentrated solution. The high

Sar-Sar-Pro	11	3 (33)
Sar-Sar-Sar	16	- (38)

*Cyclization of the tripeptide pentachlorophenyl esters in pyridine

yields found in the synthesis of *cyclo*-triprolyl can be attributed to the easy occurrence of an all-*cis* conformation of the linear tripeptide resembling the transition state of the cyclization. According to model considerations as well as NMR and CD studies it corresponds to one helix turn in polyproline I.

The yields of the *cyclo*-hexapeptides formed are given in parentheses. *Cyclo*-hexaprolyl is not formed at all because the chain ends of hexaproline are fixed in a rigid helix with two turns and therefore cannot react with each other.

A similar behaviour is shown by Sar-Pro-Pro and Sar-Sar-Pro although these peptides are less rigid and can increasingly form *cyclo*-hexapeptides. It is quite interesting that the CD spectra of these *cyclo*-tripeptides (Figure 2) resemble strongly those of the corresponding polytripeptides. From these results and from mutarotation studies we assume that *poly*(Sar-Pro-Pro) exists in two solvent-dependent conformations similar to polyproline. Hence, the peptide chromophores of the form I polymer must be similarly arranged as in the rigid *cyclo*-tripeptide which corresponds to a helix turn with the same number of units and the pitch of zero.

Introduction of 1 or 2 β-alanine residues into linear tripeptides should lead to medium-sized *cyclo*-peptides with 10, and 11 ring atoms. The phosphite cyclization of Gly-Gly-βAla and of Gly-βAla-βAla in 0.01 *M* solution, however, led to a predominant formation of the corresponding 20- and 22-membered *cyclo*-hexapeptides. In addition, the

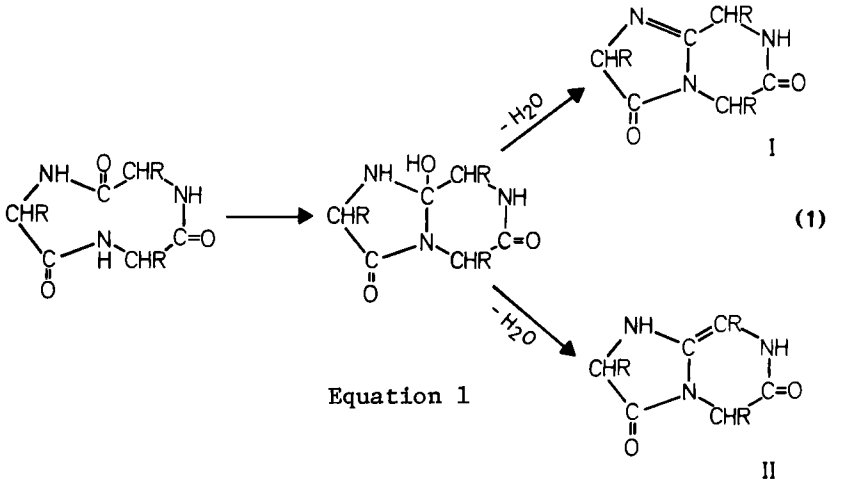
cyclo(-Pro-Pro-Sar-) ooooooo
cyclo(-Pro-Pro-Pro-) _____
in trifluoroethanol

30- and 40-membered ring homologues could again be separated by gel filtration. However, the less strained 11-membered *cyclo*-tripeptide with two β-alanine residues is readily formed, in contrast to the 10-membered *cyclo*-tripeptide of Gly-Gly-βAla which could not be found at all.

On the other hand, we succeeded in preparing this *cyclo*-tripeptide as well as others, *e.g.* *cyclo*(-βAla-Gly-Pro-), by aminoacyl incorporation from β-alanyl diketopiperazines with the intermediate formation of cyclols. The synthesis of 9-membered *cyclo*-tripeptides, however, was not possible in this way.

Instead of the *cyclo*-tripeptides, bicyclic acylamidines (I) or ketene aminals (II) have been obtained in this case by elimination of water[6] (Equation 1). They have been identified by spectroscopic methods in the case of the reaction products of the *N*-glycyl derivatives of glycine



Equation 1

anhydride and glycyl-sarcosine anhydride (→I), and of the *N*-prolyl derivatives of glycine anhydride, glycyl-sarcosine anhydride, and glycyl-L-proline anhydride (→II). Because of the close steric proximity of the peptide groups in the medium-sized ring, they are formed in a transannular reaction via cyclol intermediates.

Cyclodimerizations may also occur with tetrapeptides and pentapeptides. We have cyclized by the phosphite method various linear pentapeptides containing the sequence of gramicidin S and its analogs in which the D-Phe in position 4 is replaced by L-Phe or Gly[7] (Table II). Again, the

*Diethyl phosphite as solvent; 30 min, 100°, N_2

doubling reaction was found to depend on the peptide concentration. Moreover, the nature and the configuration of the amino acids involved play an important role. Incorporation of a D-amino acid which shortens the distance between the chain ends yielded considerably more cyclic pentapeptide than decapeptide. At the same time, steric interaction caused by bulky side chains apparently exists as can be shown by the remarkable difference in yields between the Gly and the L-Phe analogues.

Finally, the nature of the solvent seems to be very important. During the cyclization of the pentapeptide active esters of gramicidin S in pyridine, Izumiya[8] obtained relatively more *cyclo*-decapeptide than pentapeptide (ratios 55:45, 0.0003 *M*, and 68:32, 0.003 *M*, resp.) even in ten-fold higher dilution as compared with our studies. This can be explained by a stronger association occurring in pyridine rather than in diethyl phosphite used in the phosphite method. Accordingly, in the latter solvent we found reversed yield ratios of both the ring peptides under comparable concentrations (38:62, 0.005 *M*).

CHEMISTRY AND BIOLOGY OF PEPTIDES

FORMATION OF CYCLIC DIPEPTIDES AND BI- AND TRICYCLIC PRODUCTS FROM LINEAR TETRAPEPTIDES

Kirsten Titlestad. Kjemisk Institutt, Universitetet i Oslo, Oslo 3, Norway

IN THE COURSE OF OUR SYNTHESES of cyclic tetrapeptides for conformational studies,[1,2,3] we have noticed that not all linear tetrapeptides cyclize to the corresponding cyclic tetrapeptides. Cyclic dipeptides and bicyclic and tricyclic products have all been encountered.

First observed was the formation of cyclic dipeptides from several linear tetrapeptides of sarcosine combined with either alanine or glycine.[4] Their 2,4,5-trichlorophenyl esters were heated in pyridine, and the results (Table I) illustrate that the sequence of the linear tetrapeptide is important both for the size and type of cyclized products. Whenever cleavage of the peptide bond occurs, it is always the central amide bond which breaks, proving that the cyclic dipeptides are formed directly from the linear peptide and not from an initially formed cyclic tetrapeptide. It is also obvious that the second amino acid plays an important role. If it is a *N*-methylated amino acid (such as sarcosine) a *cis* configuration is about as likely as a *trans* configuration. The free amino end (I) can then easily move close to the second carbonyl group and may react with it to form the unstable cyclol (II).[5] This splits up to a cyclic dipeptide (III) and a dipeptide active ester (IV), which subsequently cyclizes to a second molecule of cyclic dipeptide. The presence of a *N*-methylated amino acid at the fourth position will, however, mean that the active ester group can also be close to the free amino end (V), and formation of the cyclic tetrapeptide (VI) will then be preferred to formation of the unstable

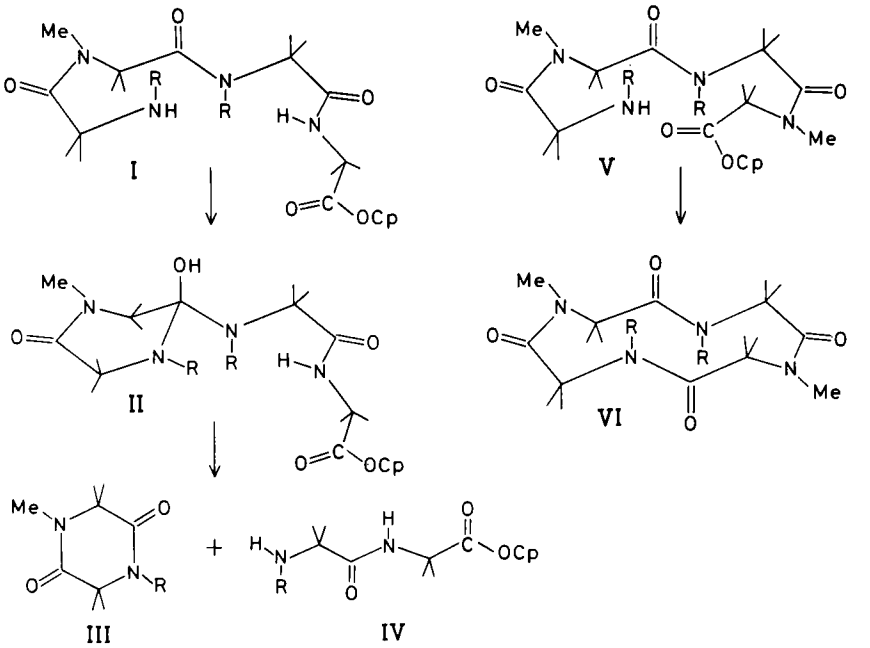
OTcp = 2,4,5-trichlorophenyl.

*Also cyclized in dimethylformamide-triethylamine at 25° with the same result, but lower yield of cyclic dipeptide.



cyclol. If, on the other hand, the second amino acid is alanine or glycine, the N-H amide bond prefers the *trans* configuration, cyclol formation no longer occurs and cyclic tetrapeptide is formed (Table I). NMR spectroscopy has proved to be a particularly useful technique for studying these cyclic tetrapeptides. The spectrum of *cyclo*(-Sar_2-L-Ala_2-) is shown (Figure 1) and clearly illustrates the favoured ring conformation with its *cis*, *trans*, *cis*, *trans* arrangement, even when, as in this case, one of the N-H amide bonds is forced into a *cis* configuration.

It was now of interest to try to prepare a cyclic tetrapeptide which does not adopt this conformation. The cyclic tetrapeptide of α-methylalanine was chosen since four trans amide bonds are needed to accommodate the four *gem*-dimethyl groups in their preferred corner positions.

Peptides of α-methylalanine[10] were activated by formation of the 2,4,5-trichlorophenyl ester. Cyclization of the dipeptide yielded the diketopiperazine with unexpected difficulty, while the larger peptides only formed polymers. The more reactive acid chloride was then prepared by treating the tetrapeptide with PCl_5 in acetyl chloride. A precipitate

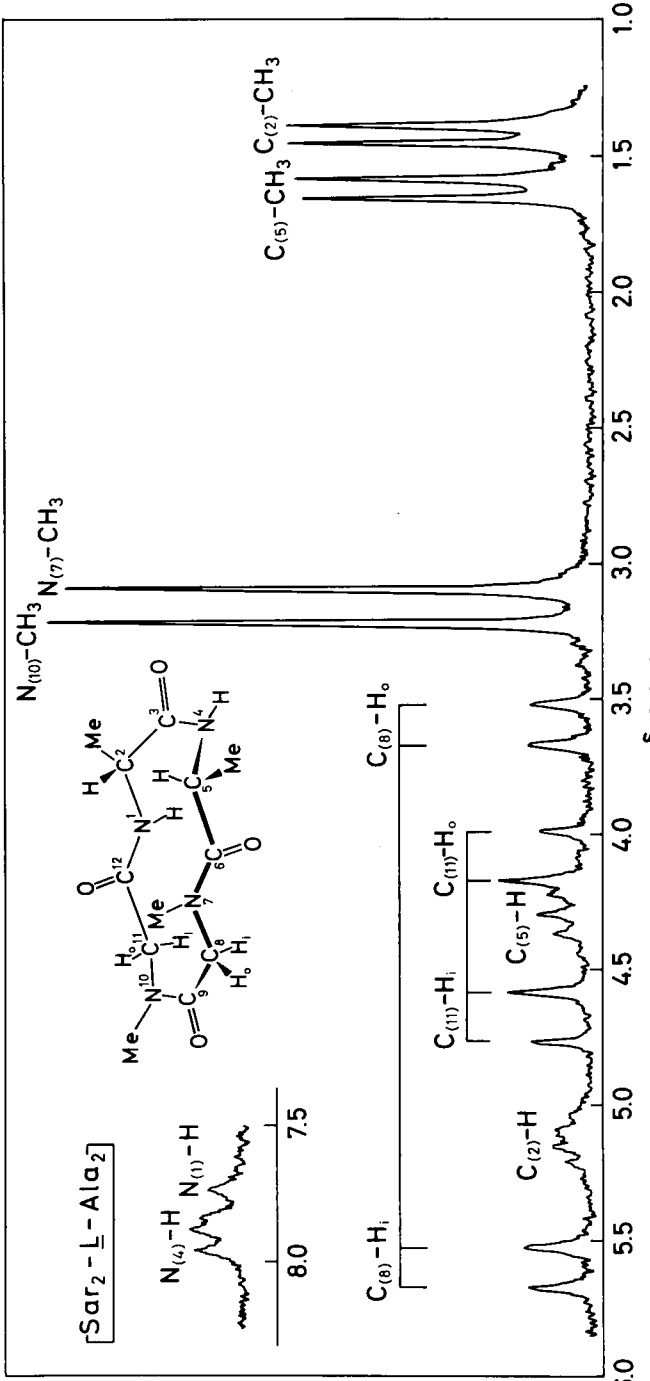


Figure 1: The 100 MHz NMR spectrum in TFA solution of *cyclo*(-Sar_2-L-Ala_2-).

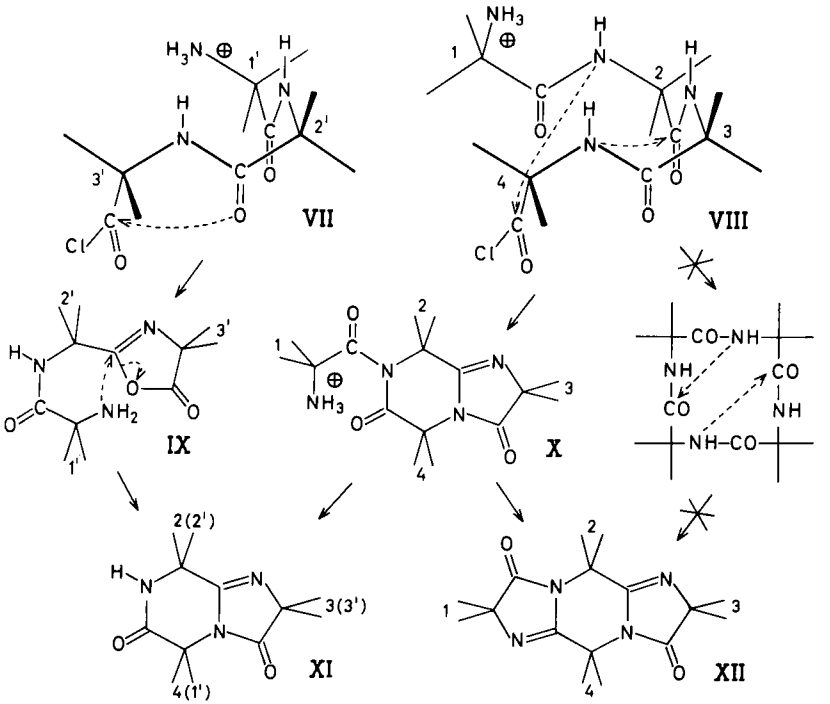
was deposited, and its infrared spectrum showed bands at 1790 (indicating an acid chloride), 1730 and 1590 cm^{-1}. Attempted cyclizations of this precipitate in pyridine, however, produced two crystalline compounds, a bicyclic imidazolone (XI) and a tricyclic bis-imidazolone (XII). Direct sublimation of the precipitate produced these products in a very low yield.



In marked contrast, treatment of the tripeptide with $SOCl_2$ formed the oxazolone (IX) characterized by an infrared band at 1820 cm^{-1}. Kenner *et al.*[6,7] had shown that this oxazolone can be cyclized to the bicyclic imidazolone (XI), but this reaction is unique to the tripeptide, as the tetra- and higher peptides formed polymers.

To gain further insight into the mechanism, the methyl groups in α-methylalanine were fully deuterated, and the tri- and tetrapeptides synthesized with one deuterated residue in various positions (Table II). ^{14}C labelling experiments[7] had shown that the last amino acid in the tripeptide oxazolone ends up in the imidazolone ring, and

Table II

Results of the Deuteration Experiments

	bicyclic XI	*tricyclic XII*

From tetrapeptide	1 : 1 : 1	2 : 2
From tetrapeptide d_6 in 1	1 : 1 : 1	1 : 2
From tetrapeptide d_6 in 4	1 : 1 : 0.2	2 : 1
From tripeptide d_6 in 3	0 : 1 : 1	- - -

this information allowed us to assign the line at 1.35 δ (Table II) to the *gem*-dimethyl groups in this ring. By analogy the lines at 1.33 and 1.89 δ in the tricyclic compound can be assigned to the methyl groups in the five- and six-membered rings respectively. The reactions of the deuterated tetrapeptide showed that the imidazolone (XI) is formed with loss of the first amino acid residue, while in the bis-imidazolone (XII) takes the specific sites indicated on the diagram. This absence of scrambling indicates that the reaction does not go via a mono cyclic tetrapeptide, and leads us to propose the reaction mechanism VIII → X → XI → XII. α-Methylalanine peptides with their N-H amide bonds will prefer to adopt *trans* configurations and the chain will be folded at the α-carbon positions. In the tripeptide (VII) with the amino end protected as the hydrochloride, the acid chloride can only attack the 2-carbonyl oxygen leading to the oxazolone (IX).

The alternative possibility, imidazolone[8,9] occurs in the case of the tetrapeptide as this then brings the acid chloride close to the amide group of the first peptide linkage and cyclization to a fused piperazine system (X) can occur. This can then either eliminate the side-chain yielding the bicyclic imidazolone (XI) or cyclize to the bis-imidazolone (XII) after liberation of the amino group.

In conclusion, it should be noted that all the cyclic tetrapeptides we have been able to prepare seem to adopt the same configuration with alternating *cis* and *trans* amide groups. It would therefore appear that this is an important factor in controlling the reactions.

CHEMISTRY AND BIOLOGY OF PEPTIDES

CONFORMATIONAL STABILIZATION OF SIDE CHAINS IN AROMATIC DIPEPTIDES

*Henry Joshua, Charles M. Deber.** Merck Sharp & Dohme Research Laboratories, Division of Merck & Co., Inc., Rahway, New Jersey 07065

Nuclear Magnetic Resonance Spectral Differences Between Diastereomeric Dipeptides

Differences in the NMR spectra of some aromatic diastereomeric dipeptide pairs have been noted for some time[1,2] and have been used to quantitatively determine racemization in coupling reactions.[3,4] In particular, these studies showed an upfield shift for the protons of an aliphatic side chain in an L-D (or D-L) dipeptide consisting of an aliphatic and an aromatic amino acid residue when compared to the L-L (or D-D) compounds.

Recently we have demonstrated[5] that this upfield shift is most pronounced for the γ-methylene protons of the aliphatic side chains in L-Phe-D-Abu† and L-Phe-D-Nva† (See Table I).

When the side chain of the aliphatic residue terminates in a polar group attached to the β position as in Asp and Asn the upfield shift of the β-methylene protons is unaffected. However, when the polar group terminating the aliphatic side chain is attached to the γ, δ or ε positions, the magnitude of the upfield shift increases and it is the γ-methylene protons which are most affected.

NMR spectra were recorded at 100 MHZ on samples of 15-20 mg dipeptide/500 µl solvent at 32° in D_2O. Chemical shifts are given in parts per million (ppm) downfield from hexamethyldisiloxane (HMS) as external standard. Values of pH were adjusted to fall between 5.5 and 7.5 and each row of dipeptides was compared at constant pH ± 0.5 pH unit. For peptides containing Asp and Glu, the pH was 3.5.

*The enantiomer D-Phe-L-Nva was used in this case.
†Due to complex spectra, values given are estimated ± 0.03 ppm.
#Proton assignments were confirmed by spin-decoupling experiments.
√Values for Δppm for ε-protons of Lys were less than 0.1 ppm.
**Cha, β-Cyclohexylalanine.

The chemical shifts of the aliphatic side chain protons for some diastereomeric dipeptide pairs are listed in Table I.

Lande[6] as well as Lemieux and Barton[7] have proposed conformations for diastereomeric dipeptides which require a trans peptide bond as well as a trans relationship of both α-hydrogen atoms in the plane of the peptide bond. We found[5] that the $J_{N\alpha}$ vicinal coupling constants of some representative L-L and L-D dipeptides are 7.5 ± 0.5 Hz, which is consistent[8] with the two general regions of preferred backbone conformations proposed by Lande.[6] In either of these two cases, if one considers the peptide bond as a virtual single bond between the two α-carbons, then the side chains would have a *trans* and *gauche* relationship in the L-L and L-D dipeptides, respectively.

The *gauche* relationship of the side chains allows shielding of the aliphatic side chain protons by the aromatic side chain in an L-D dipeptide, thus accounting for the upfield shifts. Models suggest[5] that the γ-methylene protons in particular can be positioned close to the face and center of the aromatic ring.

The increase in the upfield shift of the γ-methylene protons due to polar substituents on the aliphatic side chains indicates a closer proximity on a time averaged basis of these protons to the aromatic ring due to an *intramolecular attractive interaction* of the side chains. The nature of this interaction may be similar to that causing folding of aromatic side chains in diketopiperazines[9-14] and is probably due to an association of the polarizable π electrons of the aromatic ring with the positive end of the dipoles of the polar substituents.

This interpretation is supported by the following:

(1) This type of association has been invoked[15] to explain the forces responsible for the *intermolecular* collision complexes which display upfield shifts of the same *magnitude* as the increase in upfield shift due to the presence of polar groups in the aliphatic side chains of L-D dipeptides.

(2) The increase in upfield shift of the γ-methylene protons in going from L-Phe-D-Nva (0.39)* to, for instance, L-Phe-D-Gln (0.52) is eliminated[5] on moderate heating from 32° to 80°C indicating a weak interaction with *thermodynamic parameters* similar to those found[15] for intermolecular collision complexes.

(3) The increase in upfield shift of the side chain γ-methylene protons for L-Phe-D-Glu (0.50) at pH 3.5 over

*Chemical shift difference ppm. See Table I.

L-Phe-D-Nva (0.39) is absent at pH 11.5, *i.e.* the postulated attractive interaction giving rise to the increase in upfield shift is eliminated when the net partial *positive charge* of the polar substituent is removed as in going from carboxyl to carboxylate. The increase in upfield shift for L-Phe-D-Gln is unaffected by pH changes.[5]

(4) Elimination of the *aromaticity* of the Phe residue in L-Phe-D-Gln by hydrogenation to L-β-cyclohexylalanyl-D-glutamine brings the chemical shift of the Gln side-chain protons of the latter compound into equivalence with those of L-Ala-L-Gln[5] (see Table I).

Parallel chemical shift differences have been observed in diastereomeric dipeptide pairs of reversed sequence such as Arg-Phe and Ala-Phe[1-3,5,16] (Table II). Replacement of

Table II

Chemical Shifts and Chemical Shift Differences for N-Terminal Side Chain Protons of Diastereomeric Dipeptides

Compound	*Protons*	*Chemical Shift* L-L	L-D	*Δppm*

NMR spectra were recorded at either 60 or 100 MHZ on samples of 15-20 mg/500 μl D_2O at 32° pH ~ 2. Chemical shifts are given in part per million downfield from hexamethyldisiloxane as external standard.

*The downfield doublet of two overlapping methyl doublet pairs, the higher one centering at 1.69.

the C-terminal carboxyl group by methyl in L-L and L-D Ala-Phe gives L-Ala-(R)-Amphetamine[17] and L-Ala-(S)-Amphetamine respectively. As listed in Table II, this chemical transformation hardly affects the direction and magnitude of the chemical shift differences between the diastereomeric pairs and proves that the C-terminal carboxyl group is not necessary for the conformational preferences in these compounds to be observed.

Chromatographic Behavior of Diastereomeric Dipeptides

The conformational preferences of diastereomeric dipeptides which are proposed to explain the NMR patterns in the preceding section are also consistent with their observed relative chromatographic behavior on paper,[18] silica gel[2] and the neutral polystyrene based Amberlite XAD-2.[19]

Chromatography on silica gel and paper showed consistently[2,18] a higher R_f value indicating a *lower polarity* for the L-L isomer of a diastereomeric dipeptide pair.

On XAD-2, however, we found that L-L dipeptide diastereomers eluted first (Table III) indicating a *higher polarity*. This apparent contradiction can be resolved

Table III

Relative Chromatographic Behavior on XAD-2 Resin of Diastereomeric Dipeptides and Some Standards

Compound	*Peak Cut Number (1.5 ml/cut)*	
	L-L	*L-D*
Acetic Acid	10	
L-Ala	9	
L-Gln	8	
L-Ile	12	
L-Phe	23	
Ala-Phe	33	68
Phe-Ala	28	71
Phe-Gln	20	44
Ile-Ala	13	26

The column used was 0.9 x 30 cm filled with sieved crushed XAD-2 resin 200-325 mesh; upflow elution was employed with distilled degassed water for 40 cuts (60 ml) followed by a 1:1 linear gradient of 50 ml H_2O and 50 ml 10% ethanol. The charge consisted of 0.5 ml containing 10-20 mg dipeptide. The elution was monitored by UV or by ninhydrin spotting of cuts.

considering the adsorption mechanisms involved. Aromatic and aliphatic areas of a molecule are adsorbed by hydrophobic or van der Waals-London forces, whereas ionic groups repel the resin. It follows that an L-D dipeptide diastereomer with non-ionized side chains is more susceptible to adsorption on XAD-2 since the side chains are on the same side of the peptide bond and simultaneously accessible to the resin.

In contrast, the mechanism of adsorption on paper and silica gel involves ionic-polar interactions. There too the L-D dipeptide diastereomer is more susceptible to adsorption since it has both the N-terminal amino group and the C-terminal carboxy group on the same side of the peptide bond, and both polar groups can interact simultaneously with the polar adsorbent.

CHEMISTRY AND BIOLOGY OF PEPTIDES

DETERMINING SOLVENT EXPOSURE OF PEPTIDE PROTONS BY PROTON MAGNETIC RESONANCE

Kenneth D. Kopple, Thomas J. Schamper. Department of Chemistry, Illinois Institute of Technology, Chicago, Illinois 60616

MODELS OF CYCLIC PEPTIDE CONFORMATION based on proton magnetic resonance studies rely in part on assignment of peptide (N-H) protons to internal and solvent-exposed categories. Such assignments have been made as interpretations of temperature-induced chemical shift changes that occur in hydrogen bond accepting solvents. They have also been inferred from relative exchange rates measured in solvent mixtures containing exchangeable deuterium. Correspondence between slow exchange and small temperature coefficient is not always observed.[1-3] This should not be surprising, since neither phenomenon measures solely solvent exposure of exchangeable protons. Any hydrogen bonded proton can be expected to have a temperature-dependent chemical shift;[4] and the exchange rate depends on the probability of peptide and solvent molecules reaching an appropriate transition state, which probability is only indirectly related to the equilibrium conformation of the peptide.

A more direct measure of solvent exposure would be the effects of solvent variation on the N-H resonances, provided the resulting spectral changes can be shown not to result from conformational transitions. Effects of transfer of cyclic peptides to trifluoroacetic acid from more basic solvents have been known for some time,[5,6] but their interpretation has been doubtful because of the high acidity of trifluoroacetic acid and its known structure-breaking effects on amino acid polymers.

Urry and Pitner[7] reported recently that the resonances of the phenylalanine and ornithine protons of the cyclic decapeptide gramicidin S, solvent exposed according to both temperature dependence and exchange studies, move strongly upfield on transfer from methanol to trifluoroethanol, probably because they are no longer hydrogen bonded to solvent in the latter. The resonances of the internal leucine and valine peptide protons of gramicidin S are relatively unaffected by this solvent change.

We have been using hexafluoro-2-propanol (HFiPA) in the same kind of studies, and have examined gramicidin S, the cyclic heptapeptide evolidine,[1] the cyclic hexapeptides *cyclo*(-Gly-L-Leu-Gly-)$_2$ and *cyclo*(-Gly-L-Tyr-Gly-)$_2$,[8] and the cyclic pentapeptide, *cyclo*(-L-Ala-L-Tyr-L-Asp-Gly-Gly-d_2-).* Assignment of peptide proton resonances of the HFiPA solutions to particular residues was carried out by following the resonances through continuous change of solvent composition from a solvent in which assignments were known from H-N-C_α-H decoupling studies. Decoupling studies in HFiPA are not possible because the α-proton region is masked by intense solvent absorption. In the cases we studied, the change from dimethyl sulfoxide (DMSO) to HFiPA brings about only small changes in the H-N-C_α-H coupling constants, making tenable the assumption of no major conformational change.

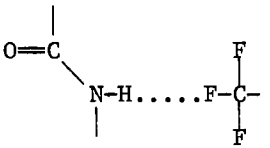
Given the conformational conclusions reached for these peptides on the bases of temperature dependences, H-N-C_α-H coupling constants, and model building, the solvent-dependent changes in chemical shift are consistent with weakened hydrogen bonding of the solvent-exposed protons in the fluorinated alcohol. On going from DMSO to HFiPA, protons considered to be internal move from 0 to 0.5 ppm downfield, and protons considered to be freely exposed to solvent move upfield up to 2 ppm. *N*-Methylacetamide moves upfield 1.3 ppm.

We have measured the peptide proton temperature coefficients of *cyclo*(-Ala-Tyr-Asp-Gly-Gly-d_2-) in HFiPA; these run parallel with the coefficients determined for DMSO solutions of the same peptide, and range from 0.3 to 6.0 X 10^{-3} ppm/degree. The existence of so large a range, which

---

*In this peptide, on which a detailed report will be made elsewhere, there appears to be a β-turn of the L-L type formed by the residues -Gly-d_2-Ala-Tyr-, with the peptide proton of the aspartic acid residue is internal, transannularly hydrogen bonded, and diamagnetically shielded by the π cloud of the Ala-Tyr peptide bond.

is no less than what we observe for DMSO solutions, indicates that there must be a temperature dependent interaction of the peptide protons with HFiPA, possibly hydrogen bonding of the type



In this connection we should report that in mixtures of *N*-methylacetamide and HFiPA the chemical shift of the amide protons is relatively independent of the mole fraction amide (at low amide), while the HFiPA hydroxyl proton resonance shifts from 4.6 ppm in pure HFiPA to about 6.2 ppm in 25 mole per cent amide. Thus the alcohol acts as proton donor and the amide as acceptor in association of the two.

Figure 1 presents a correlation between the temperature coefficient of peptide proton chemical shift in dimethyl

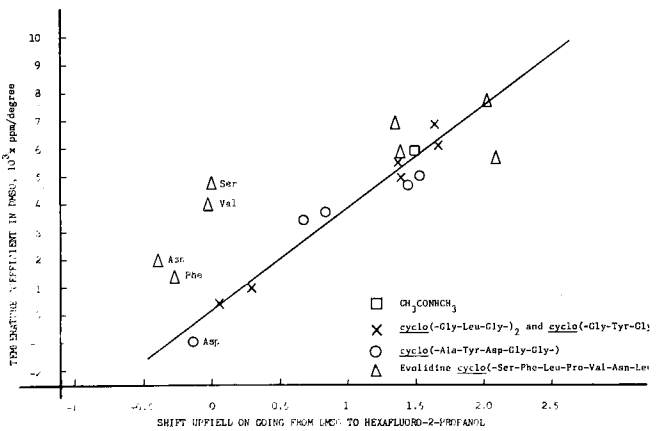


Figure 1: Correlation between shift upfield of peptide proton resonances on transfer from solution in dimethyl sulfoxide to solution in hexafluoro-2-propanol (HFiPA) at 30° and temperature coefficient of chemical shift of the same resonances in dimethyl sulfoxide solution. Shifts upfield are positive.

sulfoxide and the upfield shift on changing solvent from dimethyl sulfoxide to HFiPA. The line is a least squares fit excluding the evolidine points (triangles), and represents the correlation to be expected between the two kinds of observation in those cases where weak internal hydrogen bonds or specific solvation is not involved.

The effects of a change in solvent probably reflect the average solvent exposure of peptide protons more closely than do temperature coefficients or exchange rates, but peptides will not always be conformationally stable to the required change in environment. We recently reported[9] that hydrogen bonded association of peptide protons with the nitroxide free radical 3-oxyl-2,2,5,5-tetramethyloxazolidine produces line broadening that can be used to identify solvent-associated peptide protons at radical concentrations of under three per cent; in such measurements the perturbation of peptide environment is minor. In the gramicidin S test case, extensive broadening of the lines of the external phenylalanine and ornithine peptide protons, with relatively little change in width of the internal leucine and valine peptide proton lines, occurs at two per cent radical in methanol.

Infrared studies ($\Delta\nu_{O-H}$) of the association of 3-oxyl-2,2,5,5-tetramethyloxazolidine with phenol and with HFiPA in dilute carbon tetrachloride solution indicate that, according to published correlations,[10] the radical is a hydrogen bond acceptor of basicity comparable to acetone or an ether, but is less basic than dimethyl sulfoxide. It exhibits most obvious effects on peptide proton resonances in methanol or HFiPA solutions, although distinctions are also possible in dimethyl sulfoxide. Figure 2 illustrates the effects of added radical on the spectrum of evolidine in methanol.

It is difficult simply to express quantitatively the extent of line broadening by the radical, but we suggest expressing this as a linewidth increment, the increase in width at half height across both components of the doublet for each per cent of radical added, in the range 0-3 per cent radical. Our observations on the peptides listed earlier are that those protons with DMSO - HFiPA shifts less than zero (See Figure 1), which include the gramicidin S valine and leucine protons not in the figure, have linewidth increments comparable to that of tetramethylsilane, of the order of 1-2 Hz/% in methanol or HFiPA and 3 Hz/% in DMSO. Protons to the right of the zero line of Figure 1 are increasingly sensitive to the presence of radical (5-15 Hz/%), but, because of overlaps, there are few precisely enough known data to make more quantitative distinctions.

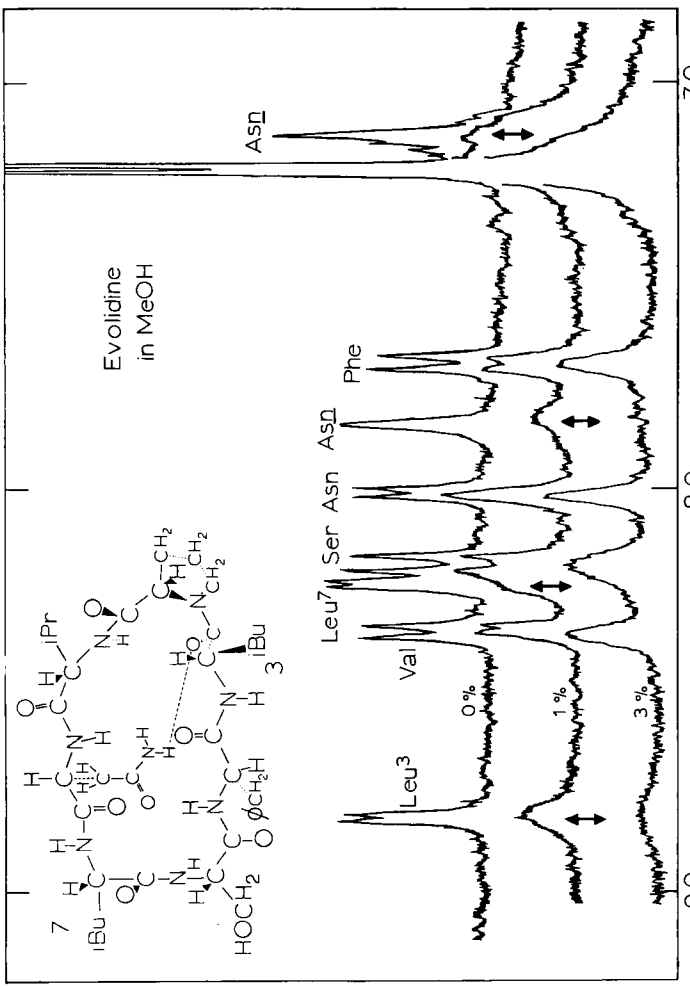

Figure 2: 250 MHz proton resonance spectrum (7–9 ppm below TMS reference) of evolidine in methanol, 30°, showing the effect of added 3-oxyl-2,2,5,5-tetramethyl-oxazolidine (0–3%) on the peptide proton resonances. The structure shown is the conformation proposed in reference 1.

It is clear from our observations that both the DMSO-HFiPA shift and the line broadening by radical measure solvent exposure of peptide protons. Therefore it is interesting to note that the temperature coefficients of the five most solvent-shielded protons in Figure 1 range from -1.0 to 4.8 x 10^{-3} ppm/degree. We suggest that these differences in temperature coefficient result from differences in stability of intramolecular hydrogen bonds, not from differences in solvent exposure. An additional source of the variation might, however, be temperature dependent changes in the average conformation of magnetically anisotropic side chain groups.

SYMPOSIUM DISCUSSIONS

Summarized by Johannes Meienhofer

THE MAJORITY OF QUESTIONS and comments about the application of proton and carbon-13 nuclear magnetic resonance spectroscopy to the study of the conformations of peptides were concerned with the difficulties and problems of assigning signals and peak positions and of interpreting spectra in terms of conformational change. This is a consequence of the present limitations, since a complete interpretation of a given spectrum is usually not possible. Additional complications arise from the fact that plots of the upfield shifts of NH signals with temperature are not always linear and occasionally even negative slopes have been observed. This renders correlations with deuterium exchange rates for the determination of external hydrogen bonds to solvent very problematic, and it was recommended to approach such studies with great care and caution. The comment was made that room temperature is actually an arbitrary point for taking NMR spectra. On cooling resonances might separate while on warming colaescense can be observed. Therefore, taking both high temperature and low temperature NMR spectra could provide a wider range of information. Several questions and comments concerned solvent effects and whether the observed spectral changes might perhaps be caused by conformational changes. The fashionable question which conformation might most closely resemble that assumed during interaction with cellular receptors remains at present open to everybody's guess. Much consideration was given to conformational analyses of oxytocin and related peptides (pp 16-24, 29-33, 35-38). It was pointed out that differences in the NMR spectra of unprotected and protected model peptides can be attributed to the protecting groups present and that the effects of

protecting groups have to be calibrated for meaningful interpretation of spectral changes. The NMR spectrum of reduced oxytocin has not yet been studied, but it was agreed that this should be very interesting. Energy calculations were applied to oxytocin as a supplementary technique for the refinement of the conformation derived from NMR studies (pp 35 - 38). Only the ϕ-ψ space in the region corresponding to the observed J_{N_α} was investigated, and it was pointed out that *ab initio* energy calculations for oxytocin or vasopressin have not been successful because of the large number of possible conformations.

For some peptides (angiotensin, cyclic proline-containing peptides) two forms have been separated by Sephadex chromatography or thin film dialysis, but unfortunately no difference in CD spectra could be observed, perhaps due to interconversion. Whether these forms were conformational isomers or due to aggregation phenomena remained unresolved. It was pointed out that for *cyclo*(-Pro-Ser-Gly-)$_2$ (p 7) an asymmetric form was observed, however, it does not become the exclusive form and occurs to the extent of 10-15% of the symmetric form. In the *retro* isomer, however, the *cis-cis* form can become almost the exclusive form when working with dimethylsulfoxide. Observations of asymmetric conformers of symmetrical molecules are very remarkable and somehow contrary to a, probably quite common, preference for aesthetically pleasing symmetrical shapes.

The question was raised whether in cyclic peptides, as *cyclo*(-Pro-Gly-)$_3$ (pp 39 to 43), which bind Na^+ or other metal ions, these ions could catalyze conformational transitions, and this might indeed be the case. Whether Na^+ is or can be incorporated into the cavity of *cyclo* (-Pro-Gly-)$_3$ in complexed form was discussed without a definite conclusion at this time.

The point was also made that carbon-13 NMR spectra will be a useful supplement to proton NMR spectra for observing *cis* and *trans* isomers of proline-containing peptides especially since the proline side-chain carbon atoms also give rise to separate resonances for the two forms. Carbon-13 NMR studies (pp 45 to 49) of myoglobin and ribonuclease, treated with [C^{13}]-enriched bromoacetate, did not yet allow the location of the carboxymethyl groups, but their signals have been very well identified.

The description of side product formation (diketopiperazines, bicyclic compounds) during cyclization of tetrapeptides (pp 59 to 65) lead to an inquiry about the driving force of diketopiperazine formation. This was left open during the discussion. In my opinion it might be explained

by the removal of the diketopiperazine (III) from an equilibrium between the unstable cyclol (structure II on p 61) and the linear tetrapeptide (I) as discussed for the decomposition of D-Val-Pro-Sar to form *cyclo*(-D-Val-Pro-) and sarcosine.[1] The suggestion was made that tetrapeptide cyclization at lower temperature than that used (115°) might minimize diketopiperazine formation. Apparently that was not the case, even at room temperature; but the overall cyclization yield was considerably smaller at lower temperatures.

FORUM DISCUSSION ON CYCLIC PEPTIDES

Session Chairmen: *Yuri A. Ovchinnikov, Elkan R. Blout.*

Panel: *F. A. Bovey, C. M. Deber, M. Goodman, C. H. Hassall, N. Izumiya, I. Karle, K. D. Kopple, H. Lackner, M. Rothe, R. Schwyzer, P. Von Dreele, R. Walter, T. Wieland.*

Edited by: *Roderich Walter.*

OVCHINNIKOV: Ladies and Gentlemen: Dr. Blout, my co-Chairman, was very kind to give this microphone to me and to suggest that I say a few words. I would first of all like to express my deep gratitude for the flattering invitation to this Third American Peptide Symposium. I was really very surprised to see so many of my European colleagues in this hall.

It is not surprising and it is highly gratifying that the organizers of the Symposium should allocate a special forum discussion to cyclic peptides. Cyclic peptides are in a special position among the peptide substances, being actually the starting points of the modern study of their linear counterparts and of the more involved proteins. The study of these compounds is not only a school for the learning of various aspects of peptide and protein chemistry in which many scientists have received their training but, moreover, different concepts have been subjected to stringent tests. Cyclic peptides attract attention in their own right. Among them we encounter multifarious biologically active compounds: antibiotics and hormones, toxins and antitoxins, alkaloids and other types of substances strongly affecting the bodily functions. Cyclic peptides have become powerful tools in the hands of biochemists and have served as the means whereby great strides have been made in the study of a number of biochemical processes. One need only mention the role of actinomycin D in the study of protein biosynthesis and of valinomycin in the study of membranes. The cyclic peptides

are also unique from a chemical standpoint. Here we meet with a wide range of ring sizes, with members containing unusual, non-protein amino acids, including N-methylamino acids and D-amino acids, and with the weak interactions resulting from the ring constraint. It is apparently not accidentally that nature has chosen a non-ribosomal path for cyclic peptide synthesis, as has been shown for example with gramicidin S. Surprises await us when studying the spatial structure of the cyclic peptides; thus, we have the pleated sheet conformation of gramicidin S, the tennis ball seam of the closely related antamanide, the disc of enniatins and the bracelet of valinomycin.

In the study of such structures, many of which are highly medium-dependent, X-ray crystallography does not assume a predominant role despite the power of this method; successfully competing with it are methods for studying the conformation of cyclic peptides in solution, and a proper balance is being struck between them. I believe that the same will be true of proteins and in the study of cyclic peptides we are breaking the trail to these coveted substances.

It is a pleasure to see here practically all the leading figures in the area of cyclic peptide chemistry. Hopefully each will avail himself of the opportunity to take the floor.

BLOUT: I will get to the more practical matters because time is somewhat limited. If you will look at the forum participants I am sure probably everybody realizes that each one of the members could speak for the full two hours and do it interestingly. However, since this forum is in the nature of an experiment, we're going to try to limit any presentation, including any formal presentation, to a maximum of five minutes and hope that the audience will participate in the discussion. Professor Ovchinnikov and I decided to divide the morning into two parts, interrelated but somewhat different, namely, the problems of synthesis of cyclic peptides and the problems of conformational determinations. So, with no further ado we should like to call on the man who has volunteered to start off the morning, Professor Rothe.

ROTHE: I wish to discuss briefly a cyclization reaction which occurs during solid-phase synthesis and which was mentioned by Drs. Khosla and Brunfeldt (see Section III).

CHEMISTRY AND BIOLOGY OF PEPTIDES

POSSIBLE SIDE-REACTIONS DURING SOLID-PHASE PEPTIDE SYNTHESIS. II.[1] REACTION BETWEEN NEIGHBORING CHAINS. FORMATION OF HYDROXY GROUPS ON THE RESIN AND THEIR CONSEQUENCES

Manfred Rothe, Jan Mazánek. Organisch-Chemisches Institut, Universität, Mainz, Germany

WE HAVE OBSERVED TWO HITHERTO unknown possibilities of formation of undesired side products during solid-phase peptide synthesis: (1) the esterification of the hydroxymethyl groups formed on the polymer support during cyclization of the peptide chain with the Boc-amino acid used for chain lengthening, (2) an aminolytic cleavage of the benzyl ester bond of the resin-bound amino acid by a neighboring peptide chain leading to peptides with extended sequences which can couple in subsequent steps. As we could show these reactions may be important during the first two steps of the synthesis; in particular, cyclization at the dipeptide stage may cause considerable difficulties during the synthesis of higher peptides. In principle, both reactions can lead to cyclic dipeptides (diketopiperazines) and consequently to hydroxymethyl groups (a) by cyclization of a resin-bound dipeptide

$$aa_2\text{-}aa_1\text{-resin} \rightarrow \boxed{aa_2\text{-}aa_1} + \text{HO-resin} \quad \text{(aa, amino acid)} \quad \text{(a)}$$

(b) by formation of a new peptide in side reaction (2) which may cyclize subsequently, e.g. during the first step of the synthesis

$$\begin{matrix} aa_1\text{-resin} \\ | \\ aa_1 \end{matrix} \longrightarrow aa_1\text{-}aa_1\text{-}\begin{matrix} \text{resin} \\ | \\ \text{OH} \end{matrix} \longrightarrow \boxed{aa_1\text{-}aa_1} + \begin{matrix} \text{HO-resin} \\ | \\ \text{OH} \end{matrix} \quad \text{(b)}$$

Reaction (b) has been investigated with resins esterified with glycine, sarcosine, and proline (capacity 0.82, 0.77,

and 0.98 meq/g, respectively). In the combined filtrates of the neutralization reaction (triethylamine in CH_2Cl_2, 10 min) after deprotection and of the subsequent washing operations (4 x CH_2Cl_2, 5 min each), we could show the presence of the corresponding cyclic dipeptides cleaved from the resin. Their amount was about 0.1% of the original substitution with the three resins examined. It increased after 20 hr shaking in CH_2Cl_2 to about 0.6% and after a total of 100 hr to about 1%. The dipeptide-resin which is not cyclized can react further in the following coupling steps, *e.g.* with the formation of chains of the type resin--aa_1-aa_1-aa_2-... As the extent of this side reaction is small with low amino acid substitution, it appears to be not significant under the usual conditions of solid-phase synthesis. However, it should be considered that it can occur in each step increasing the amounts of side products which can no longer be neglected.

From these results it may be concluded that the formation of cyclic peptides and consequently of hydroxy groups can occur especially at the dipeptide stage [equation (a)]. Indeed, in certain cases we could show the formation of considerable amounts of diketopiperazines.

In order to examine the reaction (a), all possible dipeptide-resins of glycine, sarcosine, and proline have been investigated. The deprotection and neutralization (total 30 min) reactions were carried out as usual. From these filtrates and after shaking the resin in methylene chloride (60 min) we could isolate the corresponding cyclic dipeptides in chromatographically pure state (Table I).

Forum Discussion Table I

Formation of Cyclic Dipeptides During Solid-Phase Peptide Synthesis

Dipeptide-resin	*Percent Cyclic Dipeptide (Diketopiperazine) Formation*	
	30 min	*90 min*
Gly-Gly	5	6
Pro-Gly	3.5	4
Sar-Gly	4.5	6
Gly-Pro	15	17
Pro-Pro	20	46
Sar-Pro	22	24
Gly-Sar	29	48
Pro-Sar	42	62
Sar-Sar	61	73

Their amounts correspond to the hydroxymethyl groups formed. Table I shows that the cyclization tendency depends on the nature and sequence of the amino acids. As expected, it has been found to be particularly high with *N*-alkylated amino acids and amounts up to 90% with Sar-Sar and Pro-Pro after 24 hours. The formation of diketopiperazines does not only decrease the substitution of the resins. The hydroxymethyl groups formed on the polymer support can react in each coupling step with the Boc-amino acid and carbodiimide with the formation of esters and thus become starting points for new peptide chains. Although this reaction occurs only in low yields,[1] even small amounts of amino acids bound in this way can lead to peptide mixtures which are no longer separable. Just this was observed by R. Pudill in our group during the synthesis of an antamanide sequence starting with a Pro-Pro-resin. Beginning with the tripeptide stage small amounts of the amino acid used for chain lengthening as well as further products formed from these new starting points could be detected as impurities during each of the following steps of the synthesis.

GOODMAN: In the course of a general procedure using the resin-bound amino acid dipeptide, what would you say the competition would be from cyclization? I see here you allow them to sit 30 or 90 min without adding another amino acid.

ROTHE: The usual time for neutralization and washing the substituted resin requires 30 min. I think we have to shorten this time in the Merrifield synthesis.

BODANSZKY: For which other amino acids did you check the percentage of cyclodipeptide formation?

ROTHE: We found it also when tyrosine was coupled with resin-bound serine. *Zahn* found it with Gly-Leu and Gly-Val, I believe, but it's far more pronounced with Pro-Pro.

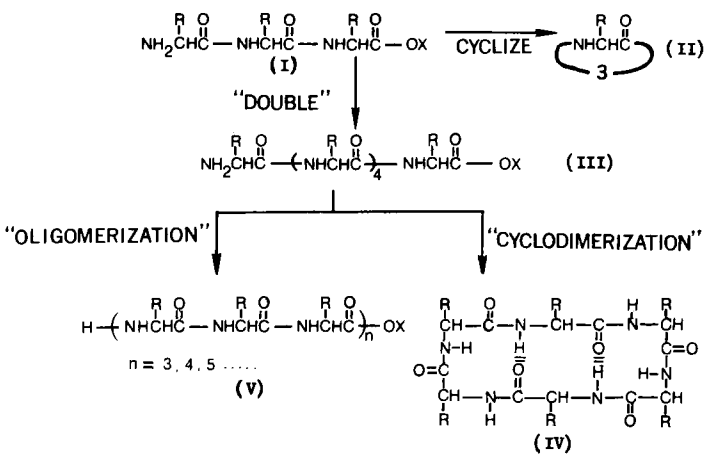
BODANSZKY: The formation of diketopiperazines from dipeptide esters is not unexpected. They will form more readily

when one amino acid belongs to the L and the other to the D configuration. This was the case in the study reported by Merrifield.

FACTORS FAVORING CYCLIZATION OF PEPTIDE CHAINS

C. M. Deber. Department of Biological Chemistry, Harvard Medical School, Boston Massachusetts 02115

SINCE THE CYCLIZATION STEP in the synthesis of cyclic peptides frequently proceeds in poor yield, it is of importance to examine the features which play a dominant role in determining the propensity of a given peptide chain to undergo cyclization. For this purpose, the qualitative mechanistic outline of a cyclization reaction (in this instance of the linear tripeptide active ester I) shown in Figure 1 is helpful. The synthesis of the cyclic peptide is viewed here in terms of a series of most-probable



Forum Discussion Figure 1: Proposed reaction pathways of linear tripeptide active ester.

events in a reaction sequence of alternative pathways. The starting tripeptide I may "cyclize" directly to give cyclic tripeptide II, it may "double" linearly to give hexapeptide active ester III, which may subsequently "cyclodimerize" to cyclic hexapeptide IV, or continue to "oligomerize" linearly to the series of extended chain peptides V. Which pathway will predominate, and what factors will determine this?

A survey[1] of the approximately 100 homodetic cyclic hexapeptides whose syntheses have been reported to date revealed that in all cases (where products were well characterized) the peptide chain contained either (a) a D residue, (b) a Gly residue, and/or (c) an imino acid residue such as proline or sarcosine. Also, only those chains consisting entirely of imino acids (Pro-Pro-Pro,[2] Pro-Pro-Hyp,[3] Pro-Pro-Sar,[4] Pro-Sar-Sar,[4] and Sar-Sar-Sar[5]) gave cyclic tripeptides. Thus, it appears that an LD sequence in the chain (or an L-Gly sequence) provides an elbow-like bend in the peptide backbone which aids in accomplishing the objective of bringing reactive amino and activated carboxyl termini into reaction proximity. Then, stabilized by intramolecular hydrogen bonds in transition states such as suggested by Schwyzer, cyclization of the chain occurs.[6] However, numerous peptide chains containing imino acids (lacking amide protons in positions necessary for intramolecular H-bonding) nevertheless give good yields of cyclic products, suggesting that a further conformational influence at or near the transition state of the cyclization may be the presence of *cis*-peptide bonds. Such bonds are "allowed" when the sequence X-imino acid is present, and models indicate that their effectiveness in bringing chain ends together may be greater than that of the LD sequence. Only when the two existing peptide bonds of a precursor tripeptide I are *cis*-allowed (*i.e.* in Pro-Pro-Pro) will cyclic tripeptide formation be an important pathway.

Note that III is the same material which is used as the starting material when cyclic hexapeptides are synthesized directly from linear hexapeptides (which is essential, of course, in the absence of sequential C_2-symmetry). In fact, about two-thirds of the known synthetic cyclic hexapeptides were prepared in this manner. It seems likely that this linear hexapeptide active ester III is a discrete intermediate in reactions leading to cyclic hexapeptide *via* cyclodimerization of tripeptide active esters, as distinguished from a concerted ring closure involving simultaneous formation of two new peptide bonds. Experimental support for this suggestion is presently lacking, however. If one

considers a hypothetical case in which cyclization leads initially to a pair of "kinetic" cyclic peptide conformations, *i.e.* conformers differing by *cis-trans* peptide bond isomers formed in varying relative ratios depending, perhaps, upon the point of ring closure of the incipient cyclic peptide, it may become possible to define the role of III. In our laboratory *cyclo*(-L-Pro-L-Ser-Gly-)$_2$ was synthesized[7] by three different routes: from cyclodimerization of Pro-Ser-Gly-ONp; from cyclodimerization of Ser-Gly-Pro-OPcp; and from cyclization of Pro-Ser-Gly-Pro-Ser-Gly-ONp. However, when the solution conformations of these three preparations were compared by 220 MHz NMR spectroscopy, identical populations of major conformer (85%, all *trans* peptide bonds) and minor (15%, asymmetric conformer, one *cis* Gly-Pro peptide bond) in two polar solvents, H_2O and DMSO were observed. These results imply that the establishment of "thermodynamic" ratios of conformers had already occurred, and perhaps cyclization and NMR studies in less polar media will be preferable.

Temperature may also profoundly influence the pathways of a given peptide cyclization reaction. Preliminary experiments in our laboratory (and results of Dale and Titlestad[5,8]) suggest that formation of cyclic tetrapeptides (from linear tetrapeptide active esters) in good yield may require elevated temperature (*i.e.* refluxing pyridine). Attempts to cyclize the same tetrapeptide chain at room temperature might produce only small yields of the cyclodimer cyclic octapeptide (and perhaps a small yield of cyclic tetrapeptide). These results reflect the difference in reaction rates as a function of temperature for the cyclization process, due to different activation parameters for each pathway, and suggest that the outcome of the overall reaction could be directed to favor a desired product by adjusting the temperature.

This discussion has presented in speculative terms how the working hypothesis shown in Figure 1 can be used empirically to make an informed estimate as to which conditions, and which configurational *vs.* conformational features will guide the cyclization reaction. Of course, the choice of the method of activation of the linear chain is also of primary importance. A more thorough understanding of the diverse factors controlling peptide cyclization mechanisms would clearly be desirable.

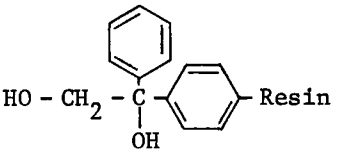
CHEMISTRY AND BIOLOGY OF PEPTIDES

PROBLEMS OF PEPTIDE CYCLIZATION ON SOLID SUPPORTS

T. Wieland. Max-Planck-Institut für medizinische Forschung, Abteilung Chemie, Heidelberg, Germany

I WOULD LIKE TO ASK SOME QUESTIONS of the audience. Everybody who works on cyclic peptides tries to get as high a yield as possible in the cyclization step, and one of the methods which seemed very promising was to synthesize the linear peptide precursor of desired length on a solid support, and then bring about the cyclization by activating the carboxyl group of the peptide on the resin. Five years ago or so, I reported with C. Birr[1] that it is possible to have the activated carboxyl group of an amino acid or peptide attached to a phenol resin which possesses a nitro group in the *o*-position or a sulfonyl group in the *p*-position. Patchornik independently reported at the same time that he had succeeded in making cyclic peptides in very good yields by the same principle. Therefore, we continued our attempts to make cyclic peptides by this method, and we proceeded in the following manner: T. Lewalter in my laboratory esterfied *p*-hydrazinobenzoic acid onto a polystyrene resin, and then the first amino acid in the solid-phase synthesis could be coupled to the hydrazino group. Proceeding stepwise, he finally got a linear peptide with the antamanide sequence. On oxidation of the substituted hydrazine with *N*-bromosuccinimide, the *N*-bound carboxyl was activated. The activation of this linkage was proved by its great reactivity with benzylamine or other amino compounds. Although aminolysis was very good, the internal cyclization reaction which occurred on deprotonation of the protonated amino end yielded only traces of the cyclic peptide.

The other approach was to introduce a handle which consists essentially of a glycol grouping:



This was shown by P. Fleckenstein, who esterified the first amino acid in a Merrifield synthesis with the primary hydroxyl of the resin-bound glycol and proceeded stepwise to get a peptide chain of 10 or more residues. The activation of the carbonyl group occurred by elimination of water by treatment with trifluoroacetic acid, which yielded an enol-ester. This enol-ester is an activated ester as was shown by virtue of its reactivity towards amines. However, also in this case no cyclization, or almost no cyclization, occurred. So, I put the question to the audience: has anyone of you ever tried to make cyclic peptides on a solid support by an approach similar to the one just described?

MITCHELL: I have been working (initially with R. W. Roeske and now with R. B. Merrifield) on the development of a polystyrene support that will allow (1) a stepwise synthesis of a linear peptide and (2) a *non-racemic* removal of the peptide from the support via an intramolecular aminolysis by the N-terminal amino group of the peptide resin. Wieland's work[2] in which the *p*-hydrazinobenzoylated resin failed to give significant cyclization complements our data which indicate that the polystyrene backbone *may* be sterically hindering the desired intramolecular aminolysis of peptide resin. We are investigating the use of hydrocarbon bridges to increase the separation of peptide and leaving group (*e.g.* *p*-nitrophenol, *p*-hydrazinobenzoic acid, catechol) from the polystyrene backbone. This approach will allow us to determine the effect of polystyrene proximity on the efficiency of cyclic peptide formation via intramolecular aminolysis of peptide resin.

PATCHORNIK: There are polymers which are very sterically hindered and you are not even successful in forming a diketopiperazine. For example, if you remove the *N*-carbobenzoxy group--or for that matter any blocking group--from a dipeptide attached to a nitrated styrene resin (Novolak), you obtain after neutralization no diketopiperazine. On treating this dipeptide active ester with a free peptide or an amino acid ester, you get peptides in nice

yields. However, there are instances where steric hindrance will interfere even in these reactions. Several years ago we reported that we were able to obtain tetraalanine, and glycyltrialanine.[3] We are checking now cyclization of longer linear peptides on "new polystyrene" derivatives hoping to achieve a good cyclization reaction. Similar experiments are being carried out in our laboratory on the formation of cyclic ketones on a polymeric support.

GOODMAN: I should like to make a comment to that. In passing, I think, Dr. Patchornik may have indicated a way of avoiding the side reaction that was alluded to by Dr. Rothe. Namely, that if one uses a Merrifield resin with sufficient steric hindrance, then one might avoid the diketopiperazine side-reaction that can arise in the dimer stage.

OVCHINNIKOV: I would like to mention that Dr. Patchornik sent his substances to our laboratory for mass spectrometry, and it proved to be a real cyclic tetrapeptide, at least in the case of *cyclo*(-Ala-Ala-Ala-Ala-).

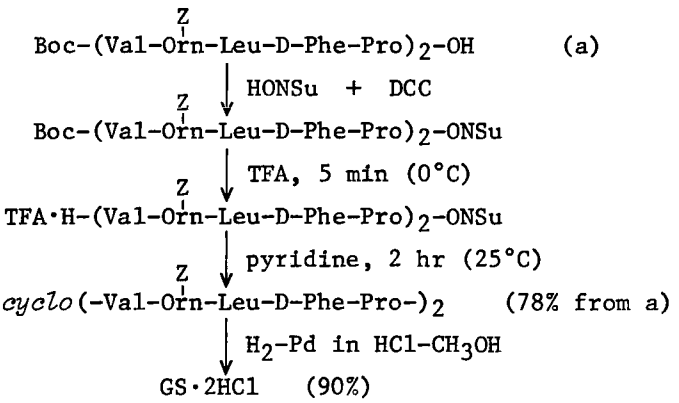
PREPARATION OF GRAMICIDIN S ANALOGS AND EFFECTS OF RING SIZE ON ANTIBACTERIAL ACTIVITY

Nobuo Izumiya. Laboratory of Biochemistry, Faculty of Science, Kyushu University, Fukuoka, Japan.

WE HAVE BEEN CARRYING OUT studies on the structure-activity relationship of gramicidin S (GS) and tyrocidines through syntheses of their analogs. Here I would like to talk on synthetic methods used to prepare GS and its analogs and then on the effect of ring-size of GS on its antibacterial activity.

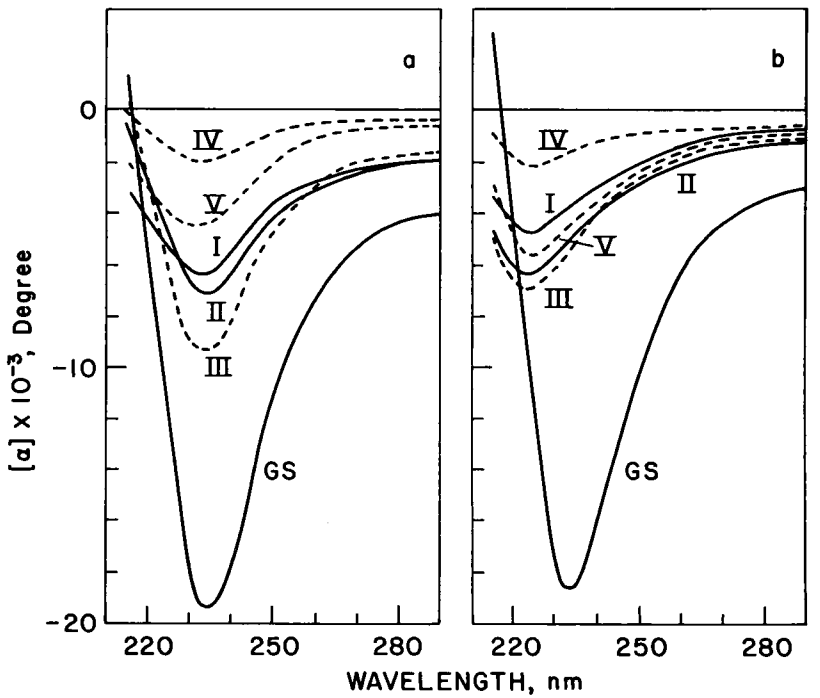
For many years we have been synthesizing GS and its analogs by cyclization of the linear peptide *p*-nitrophenyl esters in pyridine as described by Schwyzer and Sieber.[1] Yields are usually 40% to 50%. Recently, we found that the *N*-hydroxysuccinimide ester (Figure 2) or azide methods give better yields, usually 60% to 70%.



Forum Discussion Figure 2: Synthesis of gramicidin S (GS) *via* *N*-hydroxysuccinimide ester-mediated cyclization

Some years ago we synthesized *semi*GS. Recently, we prepared *sesqui-* and *di*GS as the macro-ring analogs. As the control peptides, several linear peptides were also synthesized (Table II).

The ORD of several cyclic and linear peptides was measured in ethanol and 8 *M* urea (Figure 3). The "troughs"



Forum Discussion Figure 3: ORD of cyclic and linear analogs of gramicidin S (GS). Solvent: a, ethanol; b, 8 *M* urea. I, *sesqui*GS; II, *di*GS; III, decapeptide; IV, pentadecapeptide; V, eicosapeptide.

of GS remained constant in both solvents. On the contrary, the position of the troughs of *sesqui*GS, *di*GS, linear deca-, linear pentadeca-, and linear eicosapeptide changed in 8 *M* urea. These results suggest that the conformation of the macro-ring analogs is similar to that of the linear analogs; whereas the conformation of GS is very stable even in 8 *M* urea as suggested already by Hodgkin, Schwyzer, Craig, and other investigators.

Forum Discussion Table II

Inhibitory Activity of Cyclic and Linear Analogs of Gramicidin S on Microorganisms

Compound		*Minimum Inhibitory Concentration**	
		Staphylococcus aureus	*Bacillus subtilis*
⌈→Val-Orn-Leu-D-Phe-Pro⌉	*semi*GS	>100	>100
⌈→Val-Orn-Leu-D-Phe-Pro⌉ ⌊Pro←D-Phe←Leu←Orn←Val←⌋	GS	5	5
⌈→Val-Orn-Leu-D-Phe-Pro-Val-Orn-Leu-D-Phe-Pro⌉ ⌊Pro←D-Phe←Leu←Orn←Val←⌋	*sesqui*GS	50	50
⌈→Val-Orn-Leu-D-Phe-Pro-Val-Orn-Leu-D-Phe-Pro⌉ ⌊Pro←D-Phe←Leu←Orn←Val←Pro←D-Phe←Leu←Orn←Val←⌋	*di*GS	20	10
Linear Analogs: H-(Val-Orn-Leu-D-Phe-Pro)$_n$-OH			
Pentapeptide (n = 1)		>100	>100
Decapeptide (n = 2)		50	50
Pentadecapeptide (n = 3)		50	50
Eicosapeptide (n = 4)		20	20
GS + *sesqui*GS†		5	5
GS + *di*GS†		5	2
GS + linear decapeptide†		5	5
GS + linear pentadecapeptide†		5	5
GS + eicosapeptide†		5	5

*MIC, μg/ml. †Each mixture is composed of 1:1 (by weight).

The antibacterial properties of the macro-ring analogs were similar to those of the corresponding linear analogs (Table II). For example, compare *di*GS with the linear eicosapeptide. Furthermore, the activity increased with increasing molecular size. These results afford an additional support for the contention that the decapeptide sequence in GS is important to form the rigid structure, which is required for the high and specific activity of the cyclic decapeptide.

Reference

1. Schwyzer, R., and P. Sieber. Helv. Chim. Acta 40, 624 (1957).

SCHWYZER: I think the hydroxysuccinimide method will prove to be very valuable. There is just one question: how good are the yields in the preparation of the hydroxysuccinimide decapeptide? With the nitrophenyl esters prepared by the DCCI method you have low yields, and one has to use the di-*p*-nitrophenyl sulfite to get high yields.

IZUMIYA: I believe about 70 or 80%.

CHEMISTRY AND BIOLOGY OF PEPTIDES

SYNTHESIS OF A HYDROPHOBIC ALKALI ION BINDING CYCLIC PEPTIDE

B. F. Gisin. Department of Physiology, Duke University Medical Center, Durham, N.C. 27710.

R. B. Merrifield. Rockefeller University, New York, N.Y. 10021.

THE SO-CALLED "ION CARRIERS" are able to complex with alkali ions and render them soluble in non-polar media. This quality is of great interest in the study of the ionic permeability of membranes, and it also provides a tool to investigate the relationship between primary structure and properties of a given molecule. Here we report the synthesis of a neutral cyclic peptide designed to solubilize alkali salts in an organic phase through complexation with the cation.[1]

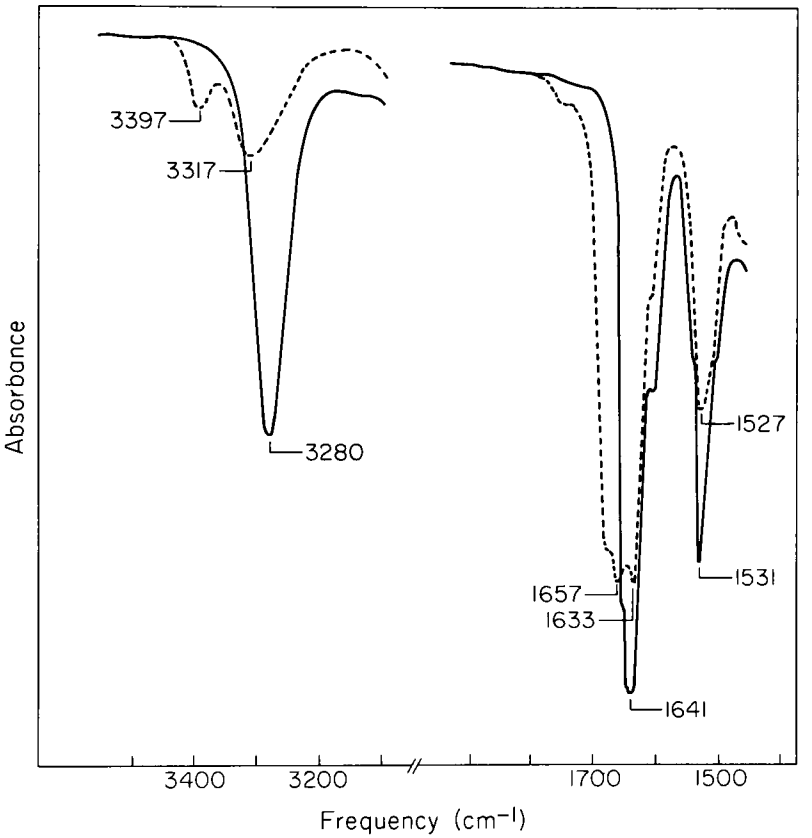
Clues necessary to devise a peptide sequence which would contain all the information to display such a property are found in the well established three-dimensional structure of the potassium complex of valinomycin, *cyclo*(-L-valyl-D-α-hydroxyisovaleryl-D-valyl-L-lactyl-)$_3$.[2,3] It exhibits the two main features of molecular architecture that are common to all of the ion carriers: there is a polar interior and a non-polar exterior. All six ester carbonyl oxygens point towards the center where they encompass the potassium ion. The backbone of this *cyclo*dodecadepsipeptide encircles the cation in three complete waves, thus forming six loops. Each peptide carbonyl is engaged in a hydrogen bond with the closest peptide NH to form a bridge across each of the loops. These hydrogen bonds are considered essential in stabilizing this symmetrical folding of the backbone. All of the side chains point outwards and thus shield the potassium ion and the hydrogen bonds from the solvent.

Space-filling models show that the choice of changes in the nature or chirality of the hydroxy and amino acid residues that would not distort the symmetrical arrangement of the coordinating atoms is very limited. Every other residue should provide an NH which can stabilize the "active conformation" through hydrogen bonding. The orientation of the side chains (which is dictated by the optical configuration of the individual hydroxy or amino acid residues) should be so chosen that they could not prevent the formation of these hydrogen bonds. The models indicate the overall geometry of the molecule is not significantly altered if the ester groups are substituted by amide groups. Nevertheless, to exclude additional NH groups that might stabilize other conformations through hydrogen bonding or decrease the lipophilic character of the compound, these amide bonds should be part of an imino acid, such as proline.

Based on these considerations we chose to synthesize *cyclo*(-L-Val-D-Pro-D-Val-L-Pro-)$_3$. The solid phase method[4] was used with the aid of an automatic Beckman Peptide Synthesizer. The tendency of H-D-Val-L-Pro sequence to cyclize to give D-Val-L-Pro diketopiperazine[5] was particularly high for H-D-Val-L-Pro-resin in the presence of a carboxylic acid.[6] Therefore, DCC was added prior to the Boc-amino acid in the coupling step. In the "regular" DCC coupling the loss of dipeptide was *ca.* 70% and with this "reversed" procedure *ca.* 10-20%. The loss of peptide chains during the synthesis was monitored by the picric acid method.[7] It indicated an amine content of the resin of 75% of its original value at the tripeptide and 65% at the pentapeptide stage, and it remained at that level throughout the synthesis. The linear dodecapeptide was purified by gel chromatography and cyclized with Woodward's Reagent K. The crystalline *cyclo*-dodecapeptide gave the expected elemental analysis and showed the calculated molecular weight of 1176 by mass spectrometry. Amino acid analysis according to Manning and Moore[8] indicated equimolar amounts of L-Val, D-Pro, D-Val and L-Pro.

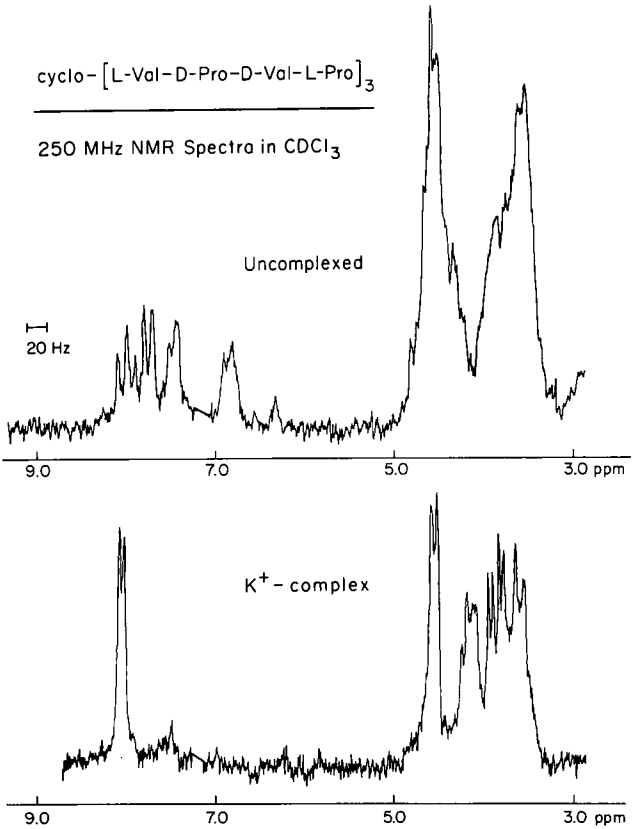
The macrocycle was demonstrated to bind alkali ions as follows. A known amount of the peptide was dissolved in CH_2Cl_2 and solid potassium picrate (which is insoluble in this solvent) was added. The yellow picrate went immediately into solution and its spectrophotometric determination indicated a 1:1 complex with the peptide. Upon evaporation of the solvent the compound was obtained in large crystals. In CH_2Cl_2-H_2O the peptide was able to extract Li, Na, K, Rb, and Cs picrate into the organic phase. In contrast, valinomycin does not extract Li or Na picrate under these conditions.

The IR spectra of the peptide and its potassium complex are shown in Figure 4. The two stretch bands of the uncomplexed peptide indicate the presence of both free (3397 cm^{-1}) and hydrogen-bonded (3317 cm^{-1}) amide hydrogens. Upon complexation these bands merge and undergo a bathochromic shift to form a single sharp band at a frequency of 3280 cm^{-1}.



Forum Discussion Figure 4: Infrared spectrum of the free peptide (broken line) and of its potassium picrate complex (solid line) in CH_2Cl_2 (*c*, 2.5 x 10^{-3} *M*). The potassium thiocyanate complex gave the same spectrum.

The NMR spectrum (Figure 5) shows the presence of several non-equivalent amide hydrogens (6.5 to 8.2 ppm) in the free peptide while there is only one NH signal in the complex (8.12 ppm).



Forum Discussion Figure 5: 250 MHz NMR spectrum of the free peptide (top) and its complex with potassium trinitrocresolate (bottom) in $CDCl_3$. The sodium complex also showed a single NH signal (δ = 7.53 ppm).

The data for the free peptide are consistent with the presence of a mixture of conformers with varying degrees of intramolecular hydrogen bonding. Complexation, on the other hand, appears to eliminate all non-hydrogen-bonded amide hydrogens in favor of one single type of hydrogen-bonded NH as would be required for a symmetrical compact structure analogous to the valinomycin-potassium complex.

Acknowledgments

We thank Dr. D. C. Tosteson for inspiring discussions, Dr. D. G. Davis for the NMR spectra, and Mr. Arunkumar

Dhundale for skillful technical assistance. Supported by NIH Grant HE 12157, US Public Health Service Grant AM 1260, and the Hoffmann-La Roche Foundation.

PATEL: I should like to ask you whether you intend replacing the proline by other amino acids? The choice of proline was very good because the conformational maps of an L-proline and an L-ester residue are similar.

GISIN: Yes, we are planning to synthesize analogs where the prolines are replaced by other residues.

WIELAND: What was the yield on the cyclization reaction, please?

GISIN: Cyclization was with Woodward's Reagent K according to a procedure by Rudinger. The yield of pure crystalline peptide was 16%.

WIELAND: Do you know something about the binding constant of the peptide with the potassium ion, as compared with valinomycin?

GISIN: In the two-phase system I have mentioned it is comparable to or higher than for valinomycin.

OVCHINNIKOV: I would just like to mention that if you replace in the valinomycin molecule any ester bonds for

N-methylamide, just replacing lactic acid by *N*-methylalanine, you can get complexation two orders of magnitude greater than with valinomycin itself. We have synthesized two such analogs.

GISIN: Did you replace all of the hydroxy acids?

OVCHINNIKOV: Both or either one of them.

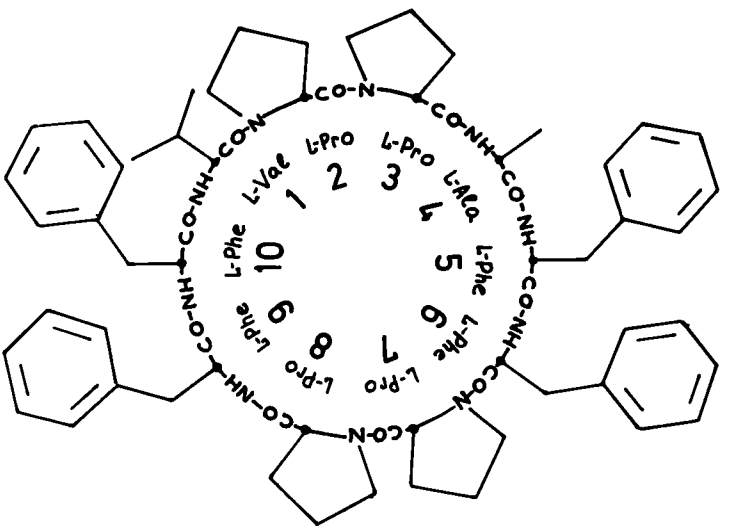
GOODMAN: We can expand on that if we take something which is a valine analog in the ester field, this is hexahydromandelic acid. It has the steric restriction of a kind of isopropyl side chain plus the ester rigidity; and then one gets what Dr. Patel was alluding to, a very specific conformational region allowed. When we get a chance, I'd like to report on our synthesis where we do the same thing with the idea of restricting the orientation of the carbonyl groups so that complexation can take place. This is alternating L-valine and D-hexahydromandelic acid cyclic hexamer.

EDITOR: Here we insert the manuscript of Yu. A. Ovchinnikov (Chairman) who courteously restrained from giving his talk to allow others ample speaking time.

THE CONFORMATION OF ANTAMANIDE IN NON-POLAR SOLVENTS

Yu. A. Ovchinnikov, V. T. Ivanov, V. F. Bystrov, A. I. Miroshnikov. Shemyakin Institute for Chemistry of Natural Products, USSR Academy of Sciences, Moscow, USSR

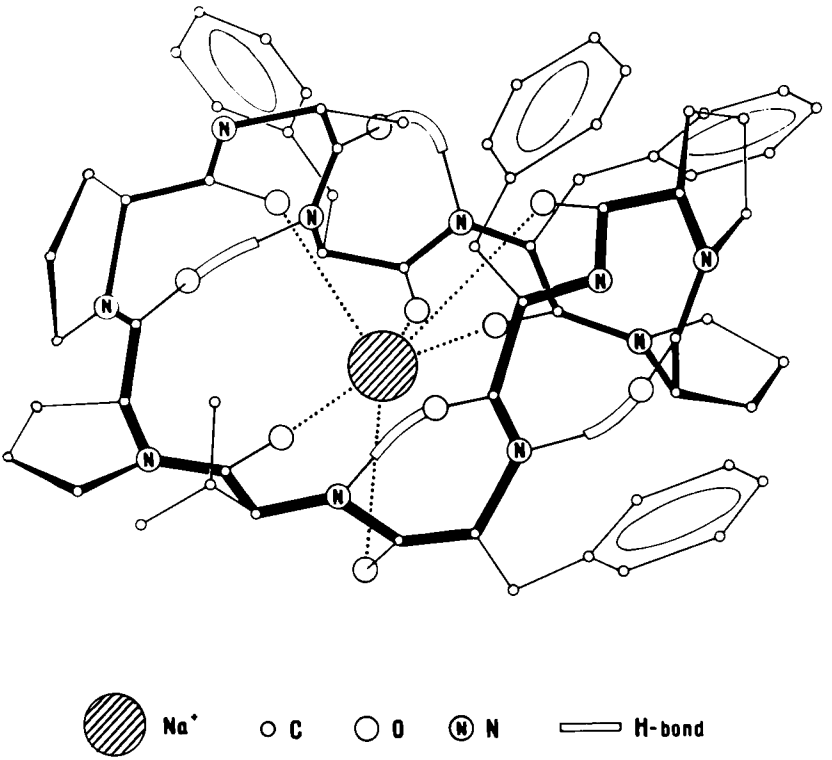
STUDIES OF ANTAMANIDE (Figure 6) are of interest not only for the purpose of ascertaining the mode of its antitoxic action, but, of course, also as a compound selectively stimulating Na^+ permeability in biological and artificial membrances. It is a truism to say that the biological



Forum Discussion Figure 6: Antamanide.

activity of peptides is highly dependent upon their conformational properties and antamanide is certainly no exception to this rule, so that a necessary condition for comprehending the peculiarities of its biological behavior is knowledge of its conformational states under various conditions.

On the basis of IR, NMR spectra and ORD studies we postulated[1] the Na^+ complex of antamanide to have the rigid conformation shown in Figure 7, stabilized by four intramolecular hydrogen bonds (IaMHB) and possessing a pseudo axis of symmetry. The sodium ion enclosed in this structure interacts more strongly with two of the carbonyls than with the other four, a fact unequivocally confirmed in a study of the ^{13}C NMR spectra of [Val^6, Ala^9]-antamanide and its Na^+ complex.[2]



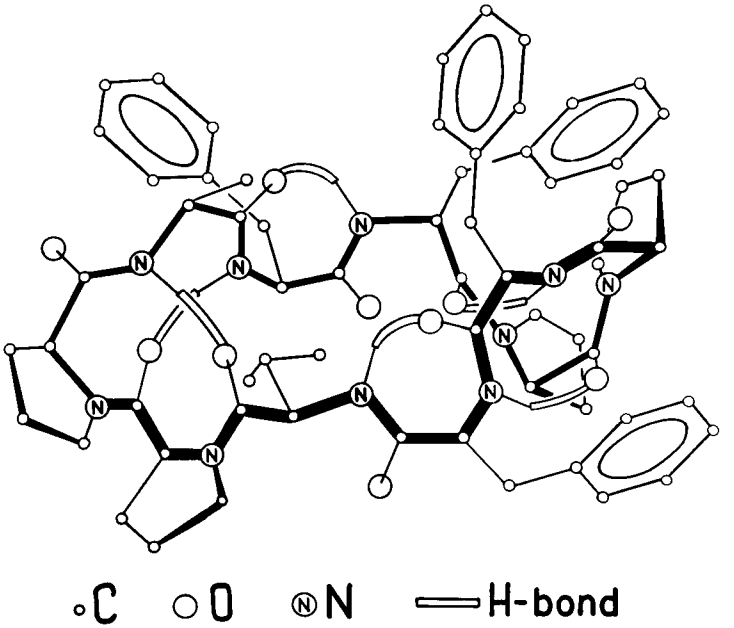
Forum Discussion Figure 7: Conformation of the Na^+ complex of antamanide (side view).

Free antamanide, on the other hand, as evidenced by spectral data, exists in the form of a highly involved conformational equilibrium whose position depends upon the composition of the medium. In non-polar media, what we have called form A, containing six IaMHB is predominant whereas on gradually passing over to alcoholic media several new forms successively appear in which the IaMHB system is more and more broken down. When passing from chloroform to dimethylsulfoxide a new form appears with *cis* amide bonds. The content of this form in the mixture can attain a value of 60%.

The structure of form A was established by systematic examination of all possible antamanide conformations possessing a twofold symmetry axis and six IaMHB. Of these the conformations were picked whose NH-CH protons were oriented in compliance with the requirements of the $^3J_{NH-CH}$ values determined from the NMR spectra, taking into account the possibility of both *cis* and *trans* amide bonds. The analysis showed that only two structures were in accord with the above requirements (all *trans* amide bonds). One of these structures was considered of little probability because of its high energy level according to the conformational energy maps and the poor agreement between the experimental and calculated dipole moments (5.2 - 5.8 D *vs.* 2.4 D). The second structure has the following parameters:

	Val^1,Phe^6	Pro^2,Pro^7	Pro^3,Pro^8	Ala^4,Phe^9	Phe^5,Phe^{10}
ϕ	-80	-60	-55	-100	60
ψ	165	-40	-40	10	-70

and the dipole moment (4.5 D) is in good agreement with the experimental values. As can be seen from Figure 8 this structure has two IaMHB of the type 3 → 1 and four IaMHB of the type 4 → 1; the latter securing the proline residues in a conformation corresponding to a 3_{10} helix. Figure 9 shows that the conformations of the peptide chain of form A and of the Na-complex of antamanide are much the same and as a first approximation one may represent transition of the complex conformation into the form A conformation as a twist of the planes of the secondary amide groups formed by Pro^3 and Pro^8. Thereby the CO^3 and CO^8 groups are shifted from the middle of the molecule to its periphery, while the NH^4 and NH^9 groups approach CO^1 and CO^6 to form with them IaMHB. Concurrently, there is a certain shift of the CO^1, CO^6, CO^5 and CO^{10} groups from the center of the internal cavity. Hence, whereas in the complex the six carbonyls are spatially nearer to one another and point

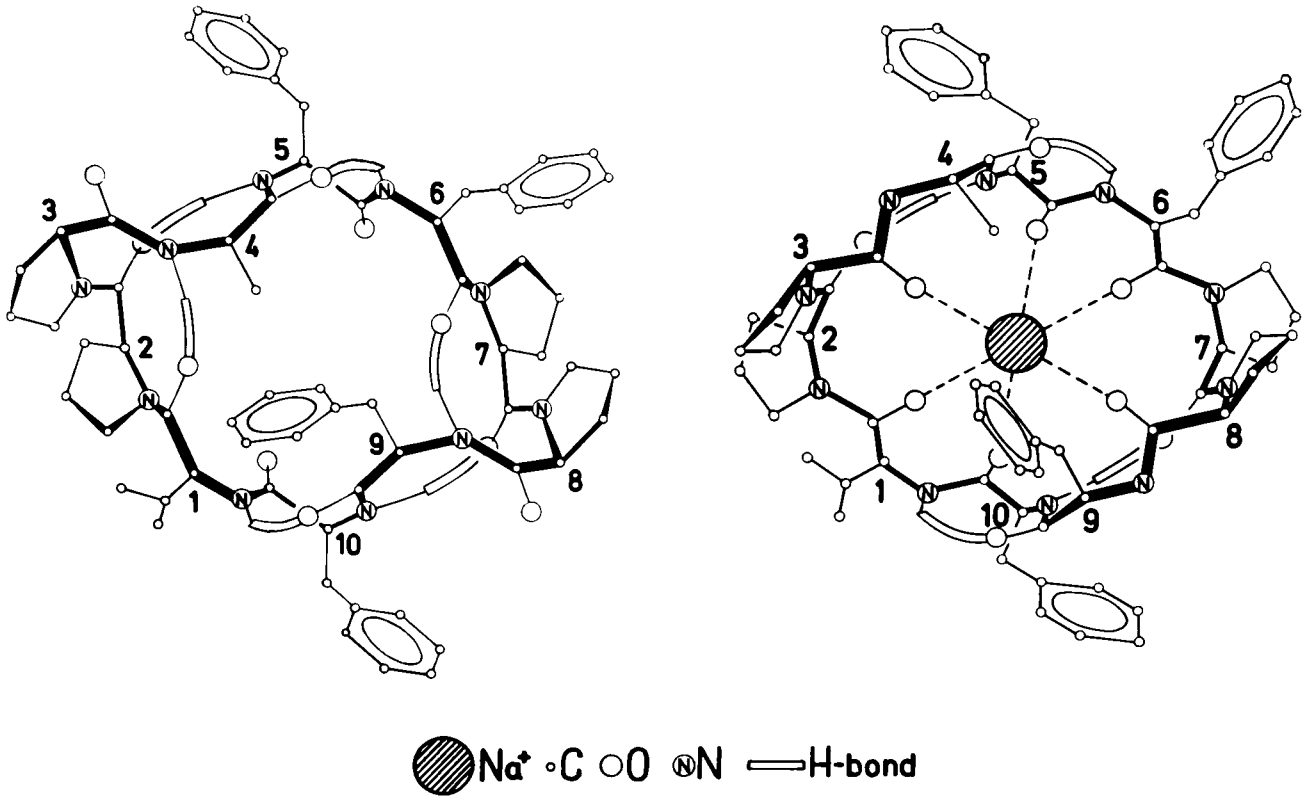


Forum Discussion Figure 8: Conformation of antamanide in non-polar solvents (side view).

within the molecule, in the free antamanide molecule these groups are much more remote from each other, excluding any significant dipole-dipole repulsion.

It is noteworthy that Tonelli *et al.*,[3] on the basis of CD and NMR data similar to ours, have arrived at quite different conclusions regarding the antamanide structure. The authors believe that antamanide has the same conformation in all the media they investigated (dioxane, chloroform, methanol, *etc.*), characterized by the absence of IaMHB and by location of all carbonyls on the same side of the average plane of the ring. However, the dipole moment of this structure, calculated on the basis of the ϕ and ψ values they presented, is 16.6 D, while localization of the amide A bands in the 3350 - 3300 cm^{-1} region of the IR spectrum leaves no doubt as to the existence of IaMHB. Thus this conformation cannot be the prevailing one in non-polar solvents, although it cannot be excluded for polar media.

Prof. Th. Wieland in a private communication has informed us that he and his coworkers[4] have now accepted the conformation proposed by us, which has been reported at the



Forum Discussion Figure 9: Conformation of antamanide in non-polar solvents and in the Na^+-complex (view along the pseudo symmetry axis).

Granada Symposium (May, 1971).[5] At the same time considering the intensity of the Cotton effects at 223 nm on the antamanide CD curves in polar solvents Wieland and coworkers suggested that the amide bonds in the Pro^3-Ala^4 and Pro^8-Phe^9 fragments were nonplanar. We believe, however, that this requires further confirmation, since the deviation from planarity should lead not only to augmented intensity but to a red shift of the $n \rightarrow \pi^*$ transition (as observed by Deber *et al.*[6] on the example of cyclo-triproline). There is no such shift in the case of antamanide.

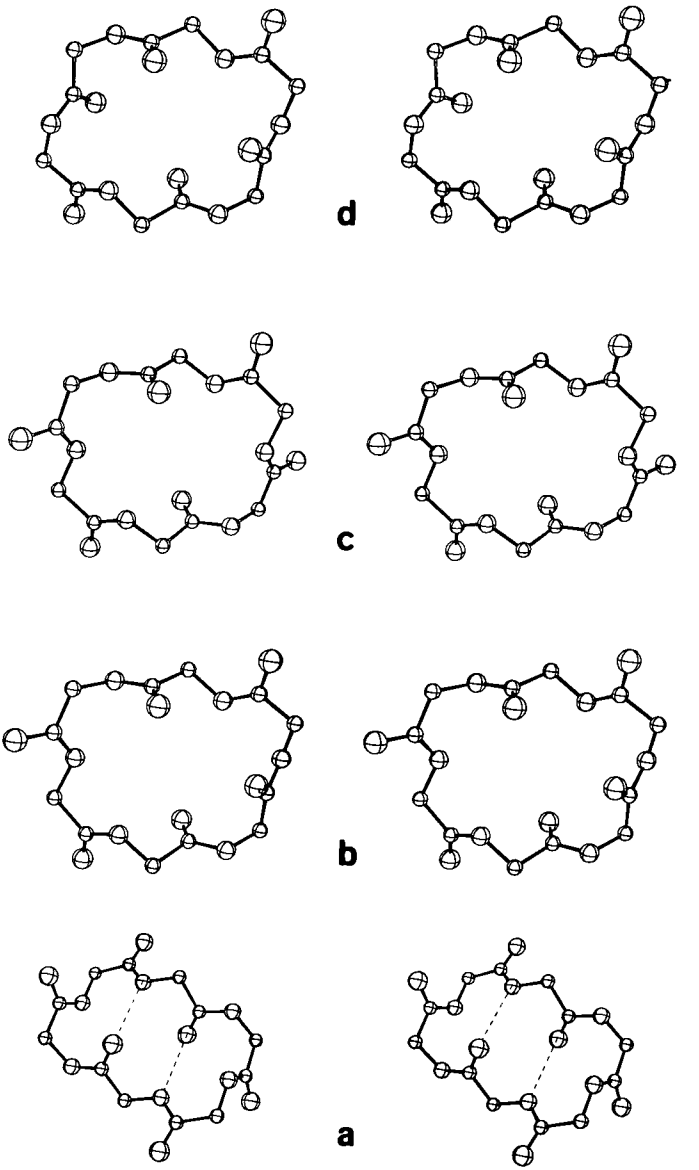
CHEMISTRY AND BIOLOGY OF PEPTIDES

CONFORMATION AND CRYSTAL STRUCTURE OF CYCLIC PEPTIDES

Isabella L. Karle. Laboratory for the Structure of Matter, Naval Research Laboratory, Washington, D.C. 20390

I HAVE JUST A FEW MINUTES to present a lot of information, so all I can really do is to bring out some highlights from the various crystal structure determinations. In some sense the great advantage of doing structure determination in the solid state is that all the atoms are in fixed positions so that the conformations and geometries can be determined very exactly. On the other hand, this is a rather artificial state for the molecule, and it is possible that its conformation is different when it is actually reacting. Figure 10 is an historic one: the structure determination was made 10 years ago. However, it is very instructive, and that is why I bring it up now. The material is cyclic hexaglycyl and in the same cell there are four different conformations for the molecule. Altogether there are 8 molecules in the unit cell, four of conformation *a*, two of *b*, and one each of *c* and *d*. Since these conformers co-crystallize, obviously, they must have fairly equivalent energies. The conformers *b*, *c* and *d* do not have any internal hydrogen bonding, whereas conformer *a* has two internal hydrogen bonds. You are now quite familiar with this particular type of internal hydrogen bonding. It must be a fairly basic characteristic of polypeptides. It has been found since in the crystalline state of several other hexapeptides. In the valinomycin molecule, a cyclic decapeptide, it occurs four times (there are also two hydrogen bonds of another type). It occurs in an analog of viomycin, which is an approximate cyclic pentapeptide. It even occurs in linear peptides. It is found in the

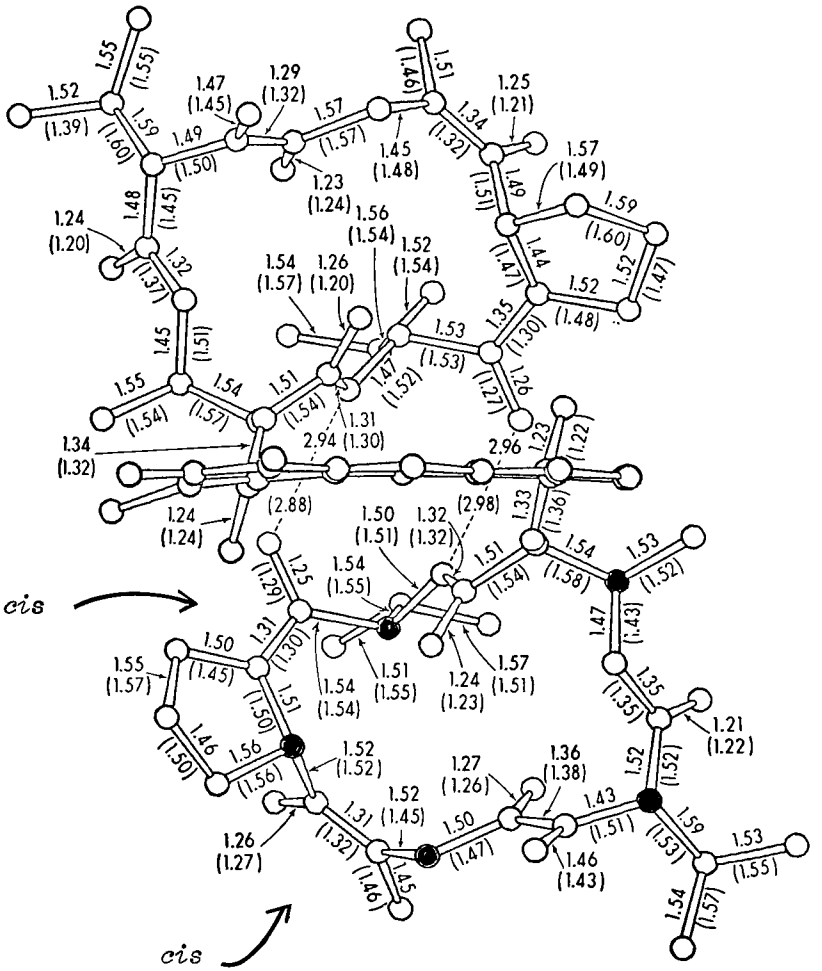


Forum Discussion Figure 10: A stereodiagram of four different conformers which exist in one unit cell of *cyclo*-hexaglycyl·1/2 H_2O. The different size spheres depict C, N and O atoms in order of size.[1,2]

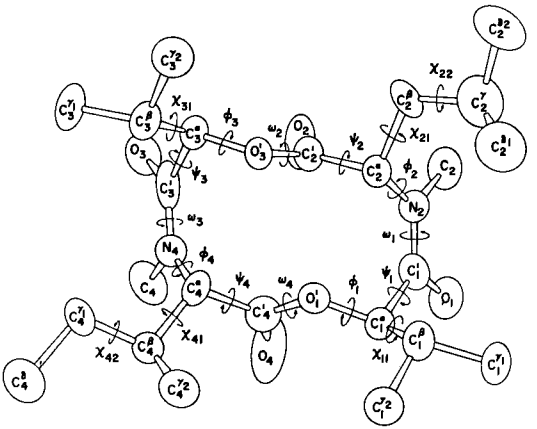
tetrapeptide from the carbon terminal of oxytocin, and since the conformation in the region of the internal hydrogen bond is the same as in conformer *a*, the linear peptide is not really linear but curled up into a *C*.

Now, if we take a look at the individual peptide groups shown in Figure 10, each one is in a *trans* conformation. What represents the difference between the conformers is the arrangement of the residues. If we examine the portion from nitrogen to nitrogen in conformer *a*, for instance, we will see a *cis* arrangement, another *cis*, then *trans*, *cis*, *cis*, *trans*. When we look at conformers *b*, *c* and *d*, we see not only a *trans* and a *cis* type of conformation, but also what I have called skew, that is, about 60° away from the *trans*. Each one of the conformers *b*, *c* and *d*, has a number of skew residues. As I have already mentioned, all the peptide groups are *trans* and are planar. Under what conditions or where do we find *cis* peptide groups? Figure 11 shows the actinomycin molecule. The structure analysis was performed by Sobell.[3] Actinomycin has two pentapeptide rings which are the same. Let us examine the bottom one. I have indicated the α-carbon atoms by the black coloration. Here you see that there is a *cis* conformation for the peptide group containing the prolyl moiety and also a *cis* conformation in the peptide group adjacent to the prolyl group. Viomycin also has a 16-membered ring similar to the one in actinomycin, but in viomycin the conformations for all the peptide groups are *trans*. Figure 12 shows a cyclic tetradepsipeptide. The α-carbon atoms are at the corners of the cyclic part of the molecule. The two ester groups (top and bottom) are in the *trans* conformation whereas the two peptide groups (on either side) are in the *cis* conformation.

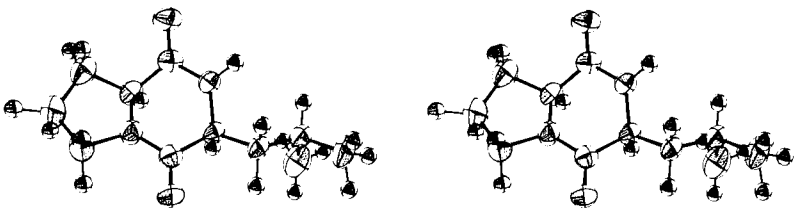
Figure 13 shows a cyclic dipeptide which, of course, contains a diketopiperazine ring. Here the peptide groups are constrained to be *cis* and they are planar, or essentially planar, as in all the studies of diketopiperazine rings of which I am aware. On the other hand, the diketopiperazine ring takes on various conformations. Sometimes it is planar and sometimes it is a twist-boat. Here the diketopiperazine ring is very definitely in the boat conformation. There is a fold along the line joining the α-carbon atoms with a dihedral angle of about 140° between the planes of the two peptide groups. There are two ways in which the side groups can be attached, either in the equatorial position or, if the diketopiperazine ring is folded in the opposite direction, in the axial position. From the small amount of information we have so far in the solid state, it seems that the attachment is in the equatorial position when the



Forum Discussion Figure 11: The conformation of the actinomycin molecule. In the lower peptide ring the shaded atoms are the α-carbon atoms.[3]



Forum Discussion Figure 12: The structure of the cyclic tetradepsipeptide D-HyIv-L-MeIle-D-HyIv-L-MeLeu.[4]



Forum Discussion Figure 13: A stereodiagram of cyclic L-Pro-L-Leu.[5]

side group is aliphatic, as in this case. Hence the two hydrogen atoms on the α-carbons are in the axial positions and quite close together. However, if one of the side groups is aromatic, the axial position for attachment appears to be preferred and the side chain with the aromatic ring is folded over the diketopiperazine ring.

I know that this presentation is a bird's eye view, but limited time prevents a more thorough discussion.

BLOUT: Thank you, Dr. Karle. It is remarkable to me that with the power of the X-ray method there has been so little discussion of X-ray results of peptides at this meeting, although we have had lots of discussion of solution conformation results. I wonder if somebody would like to comment on or to contrast the solution results in specific cases with solid-state X-ray diffraction results?

KOTELCHUCK: I was surprised, when we began doing energy calculations on oxytocin, to discover the degree of flexibility of its proposed structure--that in fact, we couldn't find a unique low energy conformation. Today Dr. Karle has reported on the many structures found in X-ray crystals, and previously there were reports of loose structures in NMR. Thus, it seems to me that we ought to consider the peptides, not as having a unique structure, but rather a range of related structures, as found with oxytocin. I think we are seeing evidence at this symposium, from different points of view, that this is the case.

PATEL: I will try to answer your question on comparison between solution, theoretical calculations and X-ray methods. For metal complexes like valinomycin-K and enniatin-Na, the solution conformations derived from spectroscopic studies coupled with theoretical calculations are in excellent agreement with the crystallographic results. The solution conformations of uncomplexed peptides and depsipeptides are highly solvent dependent. For instance, studies from Professor Ovchinnikov's and our laboratory suggest that valinomycin exists in different conformations in hydrocarbon, polar and aqueous media. These conformations which exhibit three-fold symmetry have been defined in terms of their backbone rotation angles. The crystal structure for valinomycin has just been reported and does not exhibit three-fold symmetry. The backbone rotation angles are considerably different from those predicted for the solvent

dependent conformations in solution. In this particular case, solution and crystallographic analysis are in disagreement. A comparison can be made between a conformation for actinomycin-D calculated by DeSantis[1] from conformational analysis and a crystal structure analysis by Sobell[2] on actinomycin-D deoxyguanosine (1:2) complex. There is excellent agreement between the two studies for the structure of the antibiotic. In the crystal, the two pentapeptide lactones are related by a dyad symmetry axis while the solution data and conformational calculations suggest a small nonequivalence between the conformations of the two rings.

BOVEY: I just wanted to make a very brief contribution to the subject that's been alluded to: the comparison between the solution structure as observed by NMR and the crystal structure. There is one other example (perhaps still others that I don't know of) of a simpler compound other than what has been mentioned so far, namely, *cyclo*(-D-Ala-D-Ala-Gly-Gly-Gly-Gly-). Here the crystal structure was determined by Dr. Karle and her associates a couple of years ago, and somewhat later the NMR and energy calculations were reported from our laboratory by Tonelli and Brewster. There is an obvious discrepancy between them which is perfectly all right, but just illustrates the point that the solution structure may be very different. According to NMR and according to energy calculations, the solution conformation of this molecule in dimethyl sulfoxide probably has about 24 or 25 oscillating structures between which it is equilibrating quite rapidly. None of these correspond at all to the crystalline structure, which was actually very similar to the hexa-Gly shown as *a* on your first slide (see Figure 10), if I'm not mistaken. The reason for the difference is that there are three molecules of water of crystallization in the crystals and, as Dr. Karle's work has shown, a very efficient system of hydrogen bonds: 9 hydrogen bonds to the water of crystallization, one intramolecular hydrogen bond, as shown in one of the hexa-Gly structures, and also one intermolecular hydrogen bond between peptide molecules, for a total of 12 hydrogen bonds. Multiplied by a nominal value for the hydrogen bond energy this clearly enables this structure to exist

in the crystal, although according to energy calculations it is about 16 kilocalories above the solution conformation. So here is one clearcut case of a difference between the crystal and the solution structure.

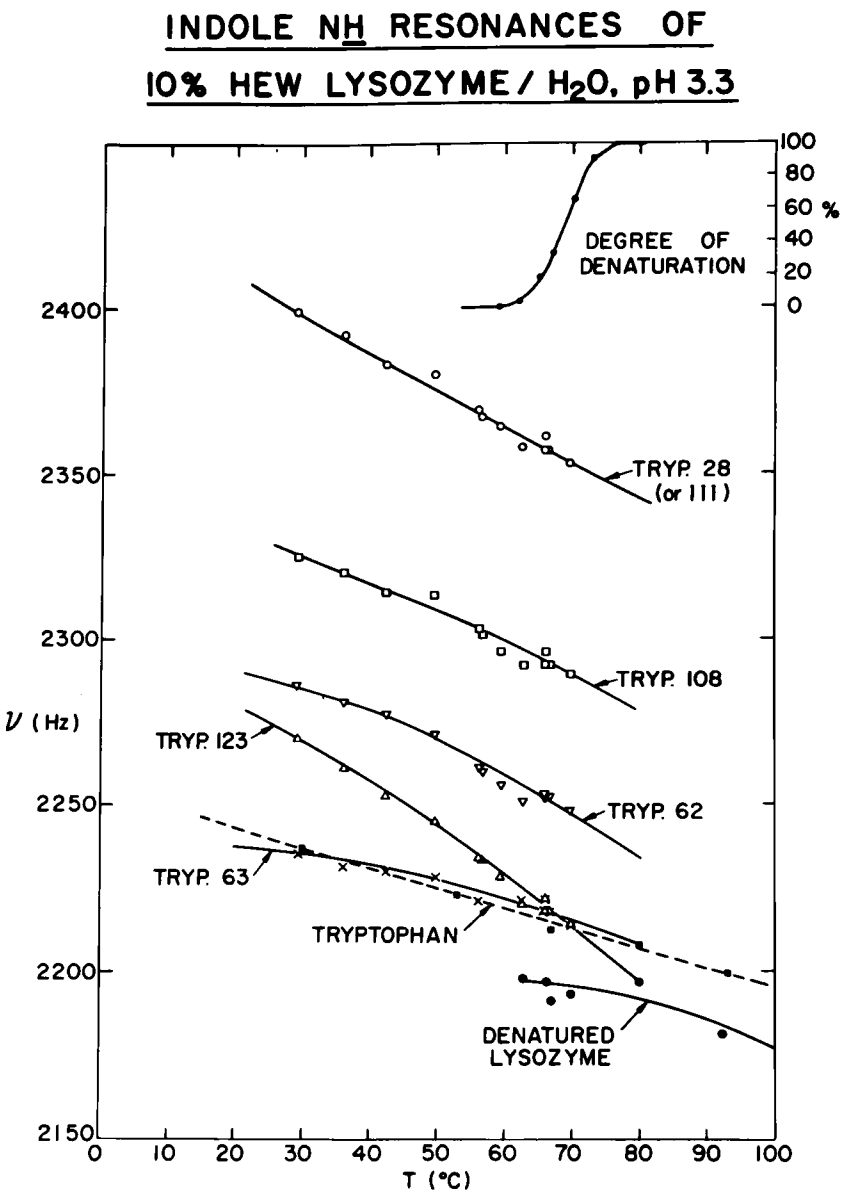
RUDINGER: I should like to propose a very primitive consideration which suggests why the solution conformation of smaller peptides might differ more from the crystal conformation that we have got used to seeing with proteins. If we assume, very crudely, that the conformation-holding forces, which operate in the "interior" of the molecule, are proportional to the volume of the molecule, and the intermolecular forces, acting superficially either in the crystal or in solution, are proportional to the surface area, then we would expect that the larger the molecule, and hence the higher the volume-to-surface ratio, the more the conformation-holding forces will predominate over the intermolecular forces and the less sensitive the conformation will be to the molecular environment (solution or crystal).

GURD: On the other hand, I think from the point of view of the protein chemist you must be very careful to leave plenty of room for differences around your surface where you're making your point. I think this has to be remembered. The argument you have here pleases me because I think what you have been putting forth fits in with what we have to contend with in the protein field all the time, *i.e.* discrepancies between crystal and solution structure and detail. You can't possibly have a structure sitting prefectly still at the active site of an enzyme while it's working, and that kind of thing.

GLICKSON: I would like to cite some experimental evidence in support of Dr. Rudinger's contention that proteins are generally more rigid than peptides, and that consequently with proteins crystal structures are better approximations to the solution structures. In the course of NMR studies of the denaturation of proteins by heat, acid, and chemical denaturants, Drs. McDonald, Phillips, and I observed that unfolding of proteins was usually slow on the NMR time scale. As a result, one generally observes in the transition range an NMR spectrum which is the weighted superposition of spectra of the native and denatured protein.[1] By contrast, most of the conformational changes of peptides that have been studied by NMR spectroscopy are fast on the NMR time scale, and throughout the transition a single

spectrum is observed which continuously changes its characteristics from the spectrum of the initial state in the transition to the spectrum of the final state. There are, of course, some exceptions to this rule; but, for the most part, peptides unfold more rapidly than proteins, which implies that more free energy must be expended to overcome the greater cohesive forces which stabilize protein conformations. This evidence together with various comparisons of protein structure in the crystalline state and in solution[2] explains why x-ray studies are generally more relevant to solution studies of proteins than of peptides. The cyclic peptide-cation complexes mentioned by Dr. Gisin are notable exceptions to this generalization.

Because of evidence that proteins such as hen egg white lysozyme, whose crystal structure has been characterized by x-ray diffraction, for the most part retain this structure in solution, it is possible to use these proteins to assess the extent to which the temperature dependence of NH resonances reflects the exposure to the solvent of NH hydrogens. Inspection of the three dimensional model of hen egg white lysozyme shows that the indole NH protons of Trp-28, Trp-108, and Trp-111 are internally hydrogen bonded, whereas those of Trp-62, Trp-63, and Trp-123 are for the most part exposed to the solvent. Recently, Drs. Phillips, Rupley, and I assigned the five resolved tryptophan indole NH resonances of hen egg white lysozyme to their specific tryptophan residues.[3] In Figure 14, we display the temperature dependence of the chemical shifts of these resonances. For comparison, we have also included the indole NH resonances of the amino acid tryptophan and the six fold degenerate indole NH resonance associated with thermally denatured hen egg white lysozyme. The indole NH hydrogens associated with the free amino acid and denatured protein are all exposed to the solvent. It is apparent from this figure that there is no obvious correlation between intra- and intermolecular hydrogen bonds and temperature dependence. Thus, the two resonances associated with intramolecularly hydrogen bonded indole NH protons (Trp-28 or 111 and Trp-108) yield similar slopes to the resonances associated with the exposed indole NH protons of Trp-62, Trp-63, tryptophan, and the tryptophan residues of denatured hen egg white lysozyme. This serves to illustrate that, at least in aqueous solution, temperature dependence of NH resonances is not a reliable criterion for distinguishing between intra- and intermolecular hydrogen bonds. Whereas these studies were confined to indole NH resonances, peptide NH resonances are expected to behave similarly.



Forum Discussion Figure 14: The temperature dependence of the chemical shifts of indole NH resonances (at 220 MHz) in H_2O.[4]

WALTER: I would like to take this opportunity to discuss two conformational assignments in the neurohypophyseal hormone field which left me unsatisfied. The first concerns one of the conformational assignments of the β-turn in the tail portion of lysine-vasopressin (LVP) in dimethylsulfoxide (DMSO) considered by Von Dreele *et al.*,[1] and the second the suggestion by Hruby *et al.*[2] that in the tetrapeptide, H-L-Cys(Bzl)-L-Pro-L-Leu-Gly-NH_2, the lone electron pairs on the sulfur and the carboxamide nitrogen might interact.

Figure 2 in Ref. 3 shows the proton NMR assignment of LVP, which is similar to that reported by Von Dreele *et al.*[4] In passing, I would like to mention that both groups have used a different approach for the assignment of LVP. Von Dreele *et al.*[1] followed the route we introduced some years ago with oxytocin.[5] That is, in their study resonances were assigned progressively from spectra of the C-terminal dipeptide, tripeptide, etc., through the acyclic nonapeptide of LVP, and then, when possible, this information was applied to the assignment of the LVP spectrum. We abandoned this approach for the assignment of the proton NMR spectra of neurohypophyseal peptides, because it suffers from some intrinsic difficulties. In retrospect, we can say that considerable changes occur in the chemical shifts of resonances of certain residues upon ring closure of the nonapeptide precursor of oxytocin to the hormone, and that similar effects were observed with other neurohypophyseal peptides. Therefore, we felt a more unequivocal way to assign the proton NMR spectrum of a previously unassigned neurohypophyseal hormone analog would be *via* a comparison of its spectrum with the assigned spectrum of oxytocin. The positions of resonances (side chain resonances and, by subsequent spin decoupling experiments, the corresponding peptide NH resonances) associated with residues present in the analogs but not in oxytocin were estimated on the basis of the study by McDonald and Phillips.[6] This approach was

found to be very satisfactory not only with LVP, but also with other neurohypophyseal peptides investigated subsequently.

Returning to the conformational analysis of the tail portion of LVP, it will be noticed that the α-CH-NH coupling constants of Lys in LVP and Leu in oxytocin are similar, as are their peptide NH temperature coefficients. The same holds for the NH peptide resonances of the Gly residues in both hormones.

This data was part of the evidence which suggested to us that in DMSO the peptide NH of Gly is hydrogen-bonded to the C=O of Cys-6 to form in LVP a β-turn comprised of the sequence -Cys-Pro-Lys-Gly-; the residues Pro and Lys occupy the corners of the β-turn. This conformation of the tail portion of LVP seems to be less preferred and much more sensitive to small changes in solvent composition than the β-turn in oxytocin, comprised of the sequence -Cys-Pro-Leu-Gly-. The conformational assignment of the latter seems to be well supported in view of the presentation by Dr. Kotelchuck, pp 35-38, in which he confirmed that conformational energy calculations starting with the proposed solution conformation of oxytocin are in agreement with the formation of such a β-turn. In addition, Rudko *et al.*[7] find an identical conformation of the crystal structure of (S-Bzl)-Cys-Pro-Leu-Gly-NH_2.

I wonder why Dr. Von Dreele or Dr. Bovey did not consider such a conformation for LVP but instead prefer as a possible structure for LVP in DMSO at room temperature one which would contain a hydrogen bond between the *trans* NH of Gly-NH_2 and the C=O of proline. On the basis of our experiences with H-Pro-Leu-Gly-NH_2, where we believe that such a β-turn does exist (*vide infra*), we would expect a large difference between the position of resonances of the *cis*- and *trans*-protons of the Gly-NH_2 in the LVP spectrum. However, the differences in chemical shift between these carboxamide protons are small and just about the same for oxytocin and LVP.

Hruby *et al.*[2] noted a large decrease in the differences of chemical shift between the nonequivalent Gly-NH_2 protons when they compared the proton NMR spectra of H-Pro-Leu-Gly-NH_2 and (S-Bzl)-Cys-Pro-Leu-Gly-NH_2. As mentioned above, it was suggested that this effect is due to interactions between the carboxamide -NH_2 and the sulfur atom. However, in the very same publication Hruby *et al.* show that Z-Pro-Leu-Gly-NH_2, which does not contain the sulfur, likewise exhibits a small difference in chemical shift in the resonances of the *cis* and *trans* Gly-NH_2 protons. Similar data were obtained when the proton NMR spectrum of (1,6-

aminosuberic acid, 2-alanine)-oxytocin, an analog in which the disulfide group is replaced by an ethylene bridge (Sakakibara *et al.*, unpublished) was recorded in DMSO. Also, in the carbon-13 NMR study of Deslauriers *et al.*[8] no changes in chemical shifts other than those associated with the Pro residue were seen in comparing Z-Pro-Leu-Gly-NH_2 with Z-Cys(S-Bzl)-Pro-Leu-Gly-NH_2. My question is whether Dr. Hruby still retains his original proposal?

HRUBY: No, not necessarily, this was only a suggestion. Clearly, one can suggest a number of other functional groups that could cause the quite small chemical shift changes (0.1 to 0.3 ppm) resulting in the nearly identical chemical shifts observed for the glycinamide carboxamide hydrogens. The important observation is that the effect is apparently caused by the presence of a group or groups attached to the proline nitrogen, and this can be taken to imply that the tripeptide and tetrapeptide you mentioned spend at least some of their time in DMSO in a conformation which enables the amino and carboxyl terminal ends of these peptides to interact. The problem, of course, as you point out is to unambiguously identify these interactions. The major point of our paper was that *cis,trans* isomerism obtains about the X-proline bond in the two peptides, and this seems firmly established.

KOPPLE: I'm not as familiar as I should be with all the ins and outs of the NMR spectra of these hormones, but some of the conclusions do seem to be dependent on the temperature dependence of the chemical shift of amide protons. I would like to ask if anyone has reasons to say that a zero chemical shift dependence necessarily means a transannular hydrogen bond? I don't think it does so necessarily. It may mean no hydrogen bond at all.

WALTER: I would agree with Dr. Kopple that a zero temperature shift does not absolutely have to be equated with the presence of an intramolecular hydrogen bond, but the assignment--I think you are referring to the intramolecular hydrogen bond assignment in oxytocin--is not based solely on the temperature plot but also on proton-deuterium exchange studies.[1]

GOODMAN: I think that we have a case where this is actually proved, that there isn't a hydrogen bond if the temperature dependence is essentially zero.

KOPPLE: That seems reasonable. If there is nothing around the hydrogen, its environment will not change with temperature.

BLOUT: In what solvent, Murray?

GOODMAN: In various solvents, the one I quote, I think, is carbon tetrachloride. It also is the case in cyclohexane.

CHEMISTRY AND BIOLOGY OF PEPTIDES

HAS THE MSH-RELEASE-INHIBITING HORMONE A PREFERRED CONFORMATION?

Roderich Walter. Department of Physiology, Mount Sinai School of Medicine, City University of New York, New York, and Brookhaven National Laboratory, Upton, New York.

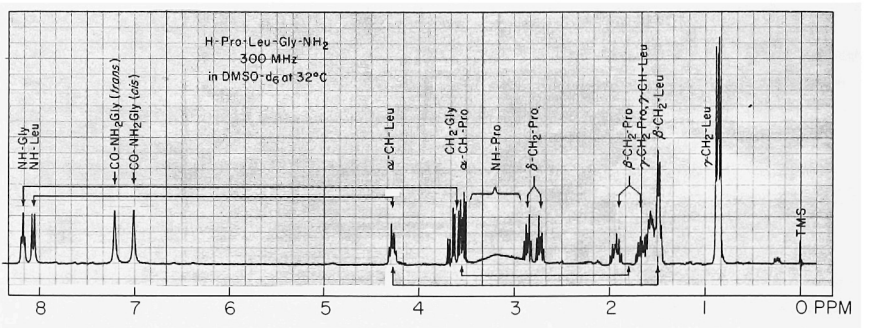
Ivan Bernal. Brookhaven National Laboratory, Upton, New York.

*LeRoy F. Johnson.** Varian Associates, Palo Alto, California.

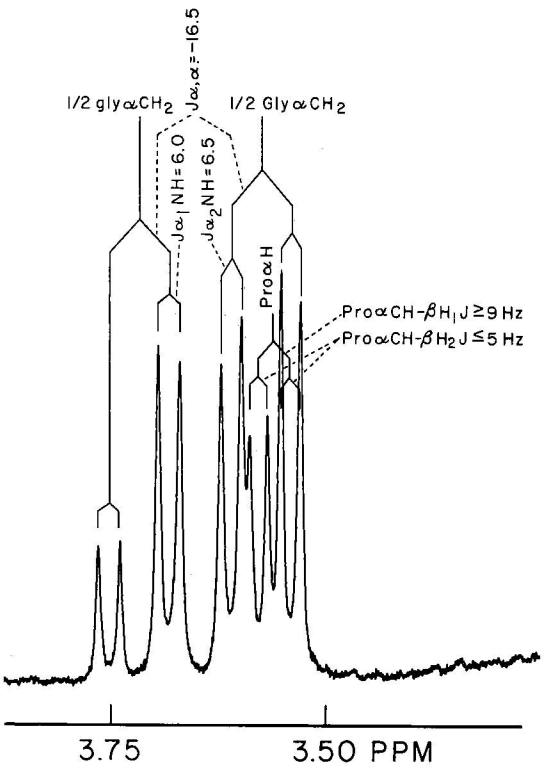
HAVING PRESENTED EVIDENCE that the C-terminal tripeptide of oxytocin is the natural factor inhibiting the release of melanocyte-stimulating hormone[1]--a finding substantiated by the isolation of an active principle with this structure from bovine hypothalami[2]--we turned to the question of whether this small peptide, H-Pro-Leu-Gly-NH_2(I) possesses a detectable preferred conformation.

The particular synthetic sample of I used in this investigation crystallized as a *hemihydrate* from water and exhibited the properties described by Zaoral and Rudinger.[3] The proton nuclear magnetic resonance (PMR) spectrum of I taken in deuterated dimethylsulfoxide (DMSO-d_6) at 300 MHz is shown in Figure 15. The assignments, determined by spin-decoupling experiments, agree with those previously reported[4] except for the chemical shifts of the α-CH proton resonance of proline (Figure 16). Splitting due to coupling between Pro β-CH and NH cannot be seen; this may indicate a J of zero, or, more likely because of the broad signal around 3.2 ppm, may result from rapid exchange of the Pro NH proton with H_2O.

*Present Address: Transform Technology, Inc., Palo Alto, California.



Forum Discussion Figure 15: 300 MHz PMR spectrum of MSH-release-inhibiting hormone.



Forum Discussion Figure 16: Expansion of Figure 15 in the 3.75 to 3.50 ppm region, which shows the chemical shifts and splitting patterns of the CH_2 of the glycine residue and the α-CH of the proline residue.

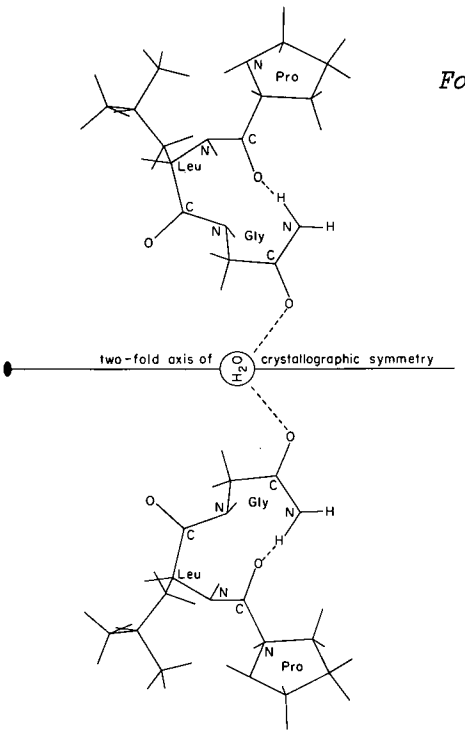
Note the conspicuously large difference in chemical shift between the resonances of the *trans* and *cis* carboxamide protons of the glycinamide moiety; in oxytocin this difference amounts to only 0.05 to 0.07 ppm.[5] We presently believe this large chemical shift difference suggests the presence of a hydrogen bond between the *trans* carboxamide proton and the C=O of proline, to form a 10-membered β-turn. In systems of at least four amino acid residues the Type I or II structures of Venkatachalam[6]--which are likewise 10-membered β-turns--seem to be generally preferred; such conformations have been found for the sequence -Cys-Pro-Leu-Gly-NH_2 in oxytocin[7] as well as for the isolated tetrapeptide[8] and for -Cys-Pro-Lys-Gly-NH_2 in LVP.[9] However if there are only three amino acid residues involved and the chemical prerequisites exist for the formation of an intramolecular hydrogen bond, then a conformation as suggested for I may be the peptide's choice. Hydrogen bonding between carboxamide protons and carbonyl oxygens has been reported in the literature, *e.g.* for succinamide.[10] The fact that the NH of proline does not enter into hydrogen-bond formation with either a carbonyl oxygen or the oxygen of a water molecule is in line with the low electrophilicity of the proton on the secondary nitrogen.

There is also preliminary evidence for the proposed conformation of I in the crystalline state. Two monomers would be held together by one H_2O molecule as shown in Figure 17, in which *both* protons of water interact with the carbonyl oxygens of the glycinamide residues of two molecules of I. An analogous situation has been described for the structure of glycyl-L-tryptophan · $2H_2O$.[11] Moreover, the model is consistent with the crystallographic data listed in Table III. Given the crystal space

Forum Discussion Table III
Crystallographic Parameters of H-Pro-Leu-Gly-NH_2·1/2 H_2O

Space Group:	$P6_122$ or $P6_522$	Density (measured) :	1.20(2)
a = b :	10.594(1) Å	Density (calculated) :	1.19
c :	50.355(8) Å	No. molecules/cell :	12 tripeptides, $6H_2O$

Chemical Composition: $C_{13}H_{23}O_4N_4$·1/2 H_2O; thus there is a crystallographic requirement that the H_2O molecules be located at two-fold axes of the space group.



Forum Discussion Figure 17: Preferred conformation of H-Pro-Leu-Gly-NH_2 monomer and its packing in the crystalline state.

group, cell constants, and density, the dimeric model has to be placed on a two-fold axis for either choice of these space groups, all of which is consistent with conformation of the dimer shown in Figure 17. A detailed X-ray crystallographic investigation of I is in progress.

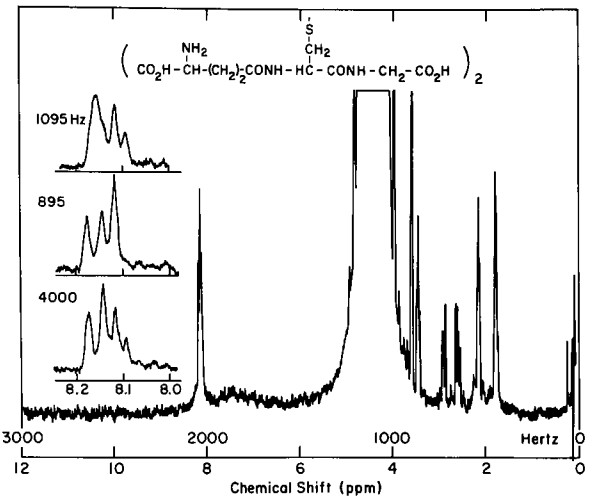
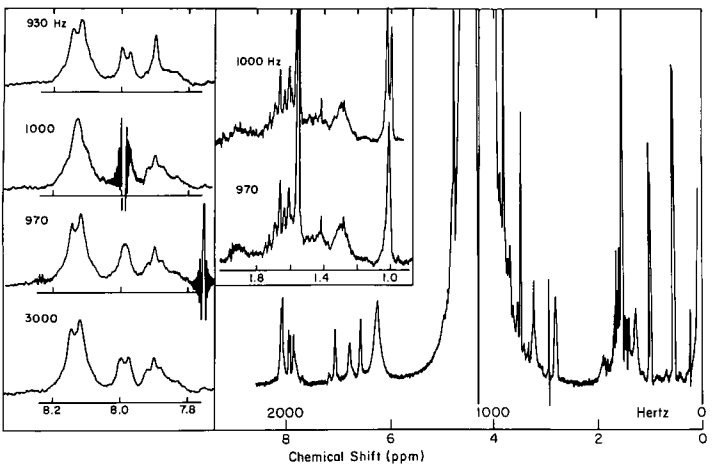
VON DREELE: Let me begin by saying that it would have been impossible to obtain the results which I am going to explain today without the cooperation of a very talented engineer by the name of Dr. Joseph Dadok. Much of the structural information which is contained in a proton NMR spectrum of an oligopeptide is obtained from the peaks arising from the peptide protons in the form of coupling constants, temperature dependence on the chemical shift, and the HD exchange data which are related to dihedral angles, hydrogen bonding, or conformational interchange. In order to use this information to obtain the 3-dimensional structure of the oligopeptide, we must be able to assign each NH peak to a particular proton in the molecule. This assignment is generally made by establishing the spin decoupling relationships between each NH peak and a C-α-H peak, and then between that C-α-H peak and the C-β-H peaks and then using the chemical shifts and the splitting patterns of the C-β-H protons to assign this set of the coupling-related peaks to a specific amino acid in the molecule. When one attempts to perform this experiment in water, one generally fails, since the C-α-H protons are located under the large H_2O peak and when you attempt to irradiate them you experience experimental difficulties with the instrument. Therefore, most of the work that has been done so far on oligopeptides has been done in dimethylsulfoxide. This has led to a number of discussions which we have heard earlier this week as to whether a structure is necessarily the same in dimethylsulfoxide as it is in water, and whether

the peptides that you recover from dimethylsulfoxide have been chemically modified by the solvent (see p 580). I would like to describe a series of decoupling experiments which have enabled us to avoid these problems by simply working directly in H_2O. The main problem in a decoupling experiment in any aqueous solution is the strong H_2O signal entering the NMR spectrometer each time the second radio-frequency field irradiates a line close to the water peak. The strong signal will usually saturate one or more amplifier stages and the lock or signal channels or both channels. A saturated amplifier stage will prevent the proper function of the appropriate channel and we lose the internal lock or obtain a distorted spectrum or both. The most probable stages to be overloaded are the last audiofrequency stages and the audiofrequency synchronistic detectors. A successful decoupling experiment can be performed if we prevent the saturation at any stage in the spectrometer by properly adjusting the amplification along the path of the signals. In the course of this work we have noted that under certain circumstances the success of this decoupling experiment is much more difficult to achieve than under others. It is difficult if the C-α-H proton is located under the H_2O peak, but not at the H_2O resonance frequency. It is easy if the C-α-H proton being irradiated is not located under the H_2O peak or is located at the resonance frequency of H_2O. I have brought along with me today two slides which will show successful experiments decoupling under the water peak, and illustrate both an easy case and a hard case. Figure 18 is that of oxidized glutathione. The NH protons are located in the region near 8.1 ppm. The C-α-H protons are located near 4.0 ppm under the very large water peak which has been truncated, and the C-β-H protons are located from 1.4 to 3.0 ppm. We have expanded the region of the NH protons and it is shown in the insert. There is a doublet from the cystine residue and a triplet from the glycine residue. The frequency 4000 Hz is an off-resonance frequency. The easy case corresponds to irradiating the glycine residue where the C-α-H protons appear out from under the water peak, and we see that if we irradiate it at 895 hertz, we obtain the collapse of the characteristic glycine triplet to a singlet. This then is an easy case where the C-α-H peak is out from under the water. Another easy case occurs when the C-α-H peak is directly at the resonance frequency of the water, since irradiation at that frequency saturates the water signal as well. An illustration of this is the cystine residue which happens to occur at a frequency of 1095 Hz which is exactly the resonance of



Forum Discussion Figure 18: PMR of oxidized glutathione in H_2O with selective NH, C-α-H decoupling.



Forum Discussion Figure 19: PMR of an Ala, Arg, Gly-containing peptide in H_2O with selective NH, C-α-H decoupling.

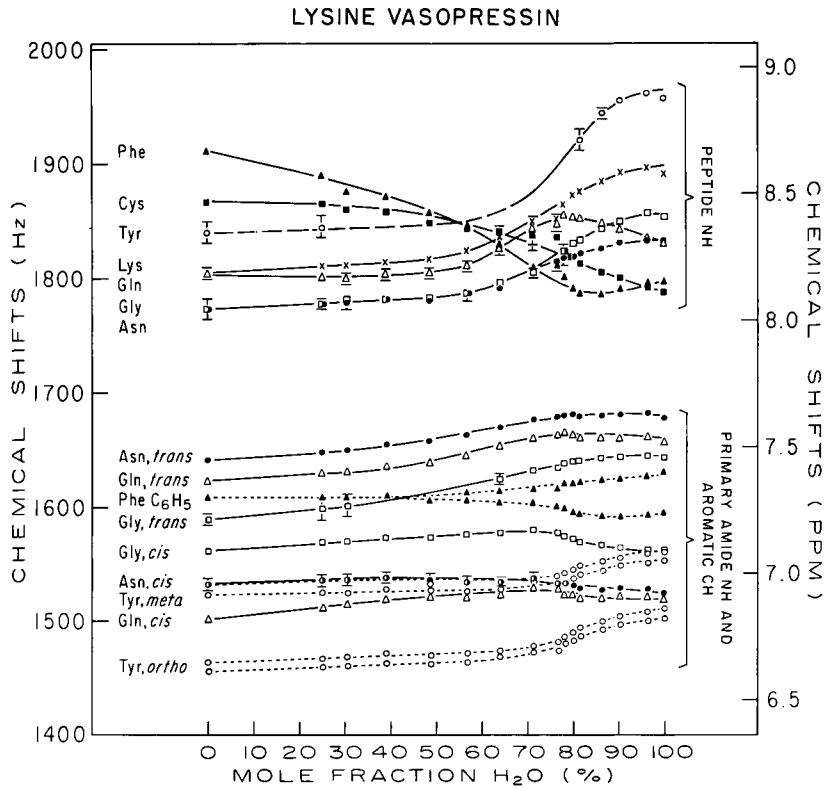
the water frequency in this spectrum. We see the collapse of the characteristic doublet of the cystine to a singlet. Figure 19 shows a more difficult case, *i.e.*, the C-α-H protons occur at intermediate frequencies. This NH region has again been expanded in the insert and 3000 Hz is an offset frequency of irradiation. We notice that if we irradiate first at 930 hertz we collapse the characteristic triplet of glycine to a singlet peak. As we move then in towards the water and irradiate at 970 hertz, we collapse a doublet to a singlet in the NH region, and if we observe the C-β-H region we see a three-proton doublet has been collapsed to a singlet. This is characteristic of the behavior of alanine, and permits us to assign this particular NH proton by a direct irradiation to the alanine resonance. If we move further in towards the water peak and irradiate at 1000 megacycles, we see a collapse of another doublet to a singlet peak. There are also changes in a region which is characteristic of the C-β-H_2 region of arginine. I have shown you today the first proton spectrum in which we were able to obtain selective NH, C-α-H decoupling of C-α-H protons located under the H_2O peak in an aqueous solution of the oligopeptide. It is no longer necessary to work in dimethylsulfoxide. We can now establish the NH to C-α-H to C-β-H spin decoupling relationships and do the concomitant peak assignments directly in the biologically interesting solvent, water.

COMMENT: Would you mind saying again what the instrumental modification was that ....

VON DREELE: There isn't any modification, it's just a very nice instrument. The success of the experiment depends in part upon the dynamic ranges of the amplifiers in the instrument. You have to be able to hold in your amplifier both the very small NH signal and the very large H_2O signal which you obtain when irradiating at frequencies where the H_2O signal has a substantial amplitude. To do this without saturating the amplifier (which will introduce beats and otherwise distort the spectrum) depends upon your ability to control the settings on each amplifier that is in the instrument. Some of the commercial instruments may have preset values on the control knobs on the amplifiers or amplifiers which do not have a large enough dynamic range. This is something which you can ascertain by going over your instrument with an oscilloscope and checking that each amplifier is not saturated. When these conditions are satisfied, you should be able to do this experiment,

just as I do this experiment, and therefore working directly in water rather than in dimethylsulfoxide.

WALTER: I would like to show you the assignment of the proton magnetic resonances of lysine vasopressin (Figure 20).



Forum Discussion Figure 20: Effect of progressively varying the solvent from pure DMSO to water, on the chemical shifts of NH (——) and aromatic CH (---) resonances of lysine vasopressin. The concentration of each hormone was maintained at 3% w/v throughout the titration and the spectra were recorded at 24°C.

This work was carried out in collaboration with Drs. Glickson and Urry. Starting with the assignments of the hormone in DMSO, the chemical shifts of individual resonances are

followed through the stepwise transition of the solvent from DMSO to water. Advantages of this titrimetric method are: a) its ability to detect conformational changes accompanying the solvent transition, and b) its applicability to the assignment of uncoupled resonances, *e.g.* carboxamide protons. Happily, several methods--each with some special advantages--seem to emerge for studying peptides in water. Besides our titrimetric method, the lowering amplification gain of the spectrometer below the saturation level as described by Dr. Von Dreele is promising and also the INDOR method as applied to peptides by Gibbons *et al.*[1] looks hopeful.

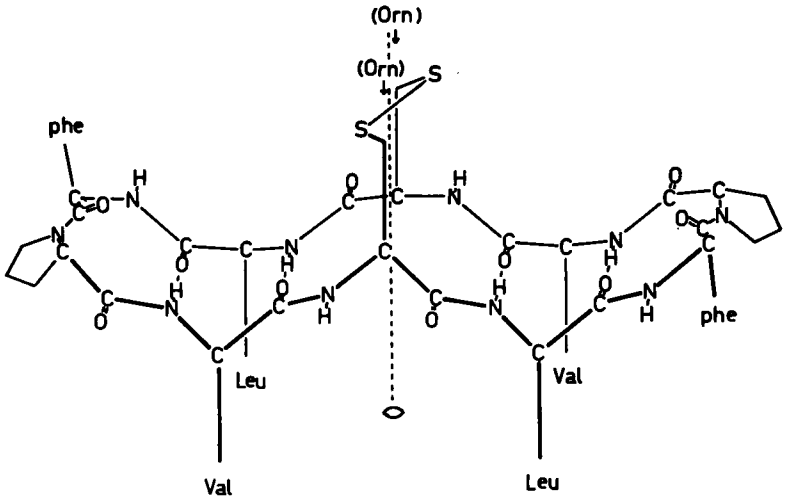
CHEMISTRY AND BIOLOGY OF PEPTIDES

SIDE CHAIN INTERACTIONS AND METAL ION COMPLEXES IN CYCLIC PEPTIDES

R. Schwyzer. Institut für Molekularbiologie und Biophysik, Eidg. Technische Hochschule Zürich-Hönggerberg, Zürich, Switzerland

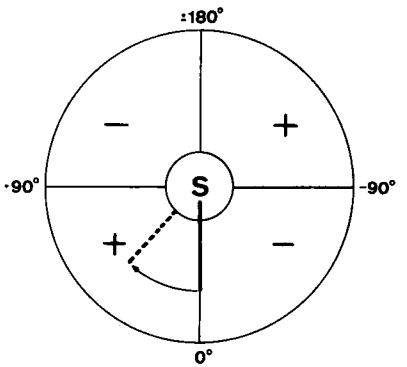
I WOULD LIKE TO SAY A WORD about work on cyclic peptides that is going on in my group in Zürich. We're using cyclic polypeptides as models for research in two directions. One is to make compounds with rather stable conformations in order to study side chain interactions. The other is to prepare cyclic peptides which can complex alkali metal ions and at the same time hopefully provide a basis for the model study of chemically driven, active ion transport through membranes.

If you build a gramicidin S molecule with the ornithines replaced by cysteines, you observe a facile, rapid formation of a cystine disulfide bond across the homodetic ring. In this [2,7-cystine]-gramicidin S, the decapeptide backbone is locked in the same secondary structure as has been observed for gramicidin S (NMR studies). The disulfide bridge appears to be stabilized in its *P* (positive, right-handed) helical configuration shown in Figure 21, because NMR indicates shielding by sulfur of the two valine NH protons (0.2 ppm) and no effect on the leucine NH. Model building suggests a large dihedral disulfide angle ($\phi_{SS} \simeq 120°$). The inherent optical activity of the disulfide chromophore expresses itself in a CD couplet with (in EtOH) $\lambda_{min} = 271.5$ nm (rotational strength, $R \simeq -12.3 \times 10^{-40}$ erg·cm^3) and $\lambda_{max} = 230$ nm ($R \simeq +58.6 \times 10^{-40}$). Another bridged compound we studied was *cyclo*-L-cystine, └Cys-Cys┘. ^1H and ^{13}C NMR indicated a boat conformation of the diketopiperazine ring and a *chiral* arrangement of the cystine disulfide bond.



Forum Discussion Figure 21: Proposed structure of [2,7-cystine]-gramicidin S. The side chains of the individual amino acid residues are indicated by their abbreviations. The side chain of D-phenylalanine (phe) on the right is meant to be pointing upwards of the ring plane.

UV spectra and model building suggested $\phi_{SS} \approx 90°$. Yet, despite chirality, no *Cotton* effect in the long wave-length region indicating disulfide inherent optical activity could be detected. These observations support the view developed on the basis of MO-calculations by Linderberg and Michl,[1] that the optical activity of the chiral disulfide bond obeys a quadrant rule, Figure 22. This implies

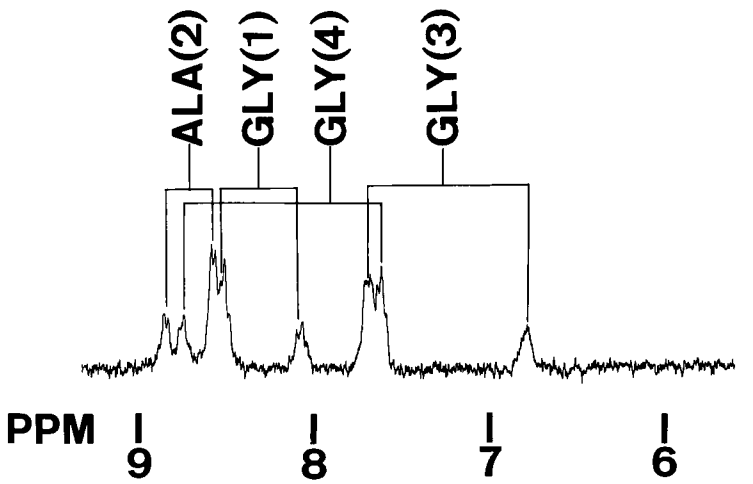


Forum Discussion Figure 22: Quadrant rule for disulfides (Newman projection along the S-S bond).

that for the prediction of disulfide chirality from CD and ORD data the dihedral angles must be approximately known. Our work has recently been described in some detail;[2] we are following it up in order to learn more about the stabilization of ring conformations by bridges.

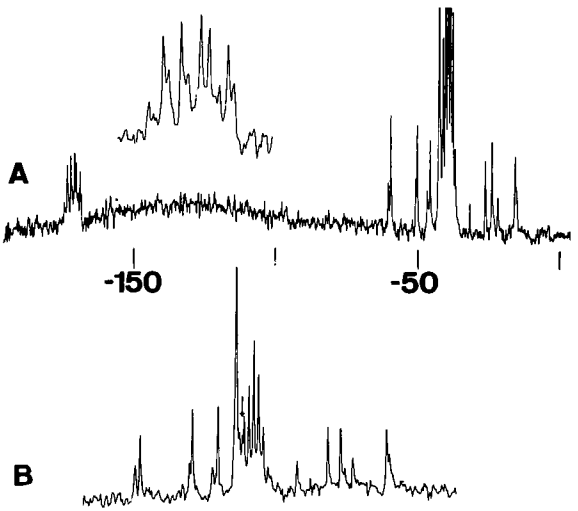
As to the other problem, we have demonstrated that *bis-cyclo* peptides of the S,S'-*bis-cyclo*-glycyl-hemicystyl-glycyl-glycyl-prolyl type can complex sodium and potassium ions. As a working hypothesis, we have assumed that the ion is "sandwiched" between the two cyclic peptide rings that are held in positions adjacent to one another by the disulfide link. If this is actually the case, then one could possibly devise a trans-membrane carrier system driven, for example, by a redox potential.[3] In order to be able to construct efficient carrier peptides, we are presently studying the conformation of such *bis-cyclo* peptides and the constituent cyclic peptides by NMR.

If we dissolve *cyclo*(-glycyl-L-alanyl-glycyl-glycyl-L-prolyl-) in deuterated dimethylsulfoxide at room temperature, we observe the ^{1}H and ^{13}C spectra of two different molecular conformations ("conformation" = "ensemble average seen by NMR technique") *M* and *m* with relative concentrations of about 2:1. Figure 23 shows that, for example, each one of the two amide protons gives rise to two signals, one



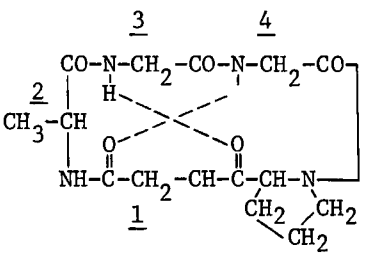
Forum Discussion Figure 23: Spectral region from 6 to 9 ppm in the proton NMR spectrum of *cyclo*(-Gly-Ala-Gly-Gly-Pro-) in DMSO-d_6 at 22°C.

with double the intensity of the other. In the ^{13}C spectra, two signals for each carbon atom can also be observed (Figure 24). Positions and temperature dependence of the amide protons indicate two solvent shielded (intramolecularly

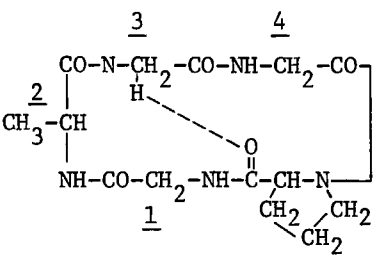


Forum Discussion Figure 24: Proton-decoupled ^{13}C Fourier-transform NMR spectrum at 25.1 MHz of *cyclo*(-Gly-Ala-Gly-Gly-Pro-) in DMSO-d_6 (the septet at 39.8 ppm corresponds to the solvent). A: 0-200 ppm region, carbonyl resonances between 165 and 175 ppm are also shown in the expanded insert. B: expansion of the 10 to 70 ppm region.

H-bonded) protons in *M* and only one in *m*. Double resonance experiments, coupling constants, and model building led to the proposition of the following conformation types:

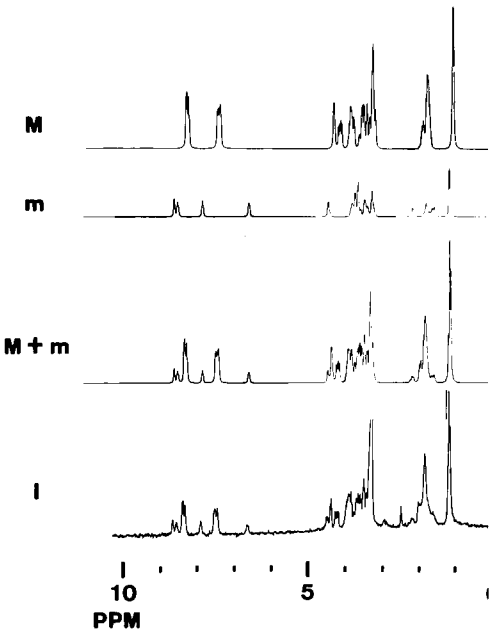


M: Gly-Pro = *trans,trans'* [see also ref. 4]



m: Gly-Pro = *cis,trans'*

The main difference between the two resides in the *cis-trans* isomerism of the Gly^3-Pro peptide bond. The relatively high activation energy of this transition offers a plausible explanation for the slow rate of $M \rightleftarrows m$ interchange. From the occurrence of separate NMR lines for the two species (calculated spectra see Figure 25) and from the observation in INDOR experiments of double resonance effects mediated between corresponding resonances of the two species by the interchange process, we conclude that the lifetime of the major species, *M*, must lie between 2×10^{-2} and 3×10^{-1} sec.



Forum Discussion Figure 25: Comparison of the spectra calculated for the *M*, *m*, and *M+m* conformers of *cyclo* (-Gly-Ala-Gly-Gly-Pro-) with the observed (I) proton NMR spectrum.

A comparison of the ^{13}C spectra of *M* and *m* in Figure 24 reveals particularly large chemical shift changes of the proline C_β and C_γ resonances in the range of 22 to 32 ppm. In the *trans* prolyl situation of *M* they are rather close to one another (24.3 and 26.7 ppm), in *cis*, *m*, they are further separated (22.2 and 32.1 ppm). Such differences

are to be found in analogous cyclic peptides containing proline, of which we have investigated four others. We therefore believe that these shifts will prove to be of great diagnostic value in the future.

It appears that in S,S'-*bis-cyclo*(-glycyl-hemicystyl-glycyl-glycyl-prolyl-) the two rings are also present as conformers *M* and *m* in DMSO, and they undergo considerable changes on complexation with potassium ion. For details of this work see ref. 5, 6.

OVCHINNIKOV: What about selectivity of complexation?

SCHWYZER: Dr. Simon has shown that the sequence is: $K^+ > Na^+ > Li^+$. Using synthetic bilayer membranes, we believe that Rb^+ is better yet.

COMMENT: Does sulfur contribute to complexation?

SCHWYZER: We're not considering this in our model. It might be, although I don't know.

BOVEY: What does the shielding anisotropy of a disulfide bond look like? Is this known from other studies?

SCHWYZER: No, it's not known from other studies. We get a shielding of the valine NH by 0.2 ppm.

ON CONFORMATIONS AND INTERANNULAR RELATIONSHIPS OF FREE AND ONE-SIDEDLY FIXED PENTAPEPTIDE LACTONES

Helmut Lackner. Institute of Organic Chemistry, University of Göttingen, Göttingen, Germany

DUE TO THEIR UNIQUE STRUCTURE containing two closely adjacent, one-sidedly fixed peptide groups, actinomycins (Figure 26, IIa) and their precusors are excellent objects

for NMR investigations on conformation and peptide/peptide relationships. The indispensable α,β-specific assignments of the NMR spectra were reliably achieved by the aid of various selectively labelled deuterio compounds[1] (Figure 27).

If not linked to actinocinyl the linear intermediates of the pentapeptide lactone groups show well analysable spectra ($CDCl_3$)[1] and a remarkable continuity of characteristic data, when the chain is lengthened. This suggests a preservation of partial conformations up to the pentapeptides. Subsequent cyclisation changes the spectrum considerably.

The *free pentapeptide lactones* (I) dimerize in dry benzene by face-to-back association;[2] a redoubling of NMR signals and molecular weights is observed. The very sharp and characteristic spectra of I (and of related cyclic peptides) in chloroform[1] and acetone (Figure 27) differ from each other to such an unusual degree (δ- and J-values, temperature dependence, hydrogen exchange), that two distinct conformations of the peptide ring must be assumed: the *C* (chloroform)- and the *A* (acetone)-form.* In mixtures of the two solvents or in acetone (or methanol)-water both types of spectra appear simultaneously, but only normal molecular weights are obtained in these cases (osmometry of the NMR solutions). No comparable effects could be observed with *linear* pentapeptides.

On conversion of the pentapeptide lactones into *actinomycines* (Ia→IIa) (methanol-water) both the C- and the A-conformations are disposable. NMR measurements (Figure 28 and others) show, that only the *A*-conformation is accepted by the actinomycins and--corresponding to the crystalline form[3]--the α- and β-peptide rings are arranged in a face-to-face position ("axial symmetry"). The spectra of the *cyclo*peptide groups now linked by pairs to the actinocinyl chromophore prove to be no more solvent dependent than usual[1,4] (rigid conformation of the whole molecule). The A-type conformation of the peptide rings is mainly stabilized by interannular NH(Val)-hydrogen bridges, the chromophore primarily serves as a clamp.

According to NMR results and chemical properties[1] this mutual stabilization is considerably minimized, but not cancelled, if *one* of the peptide rings is opened [actinomycin acid (=IIb) monolactones or their esters]. The *cyclo*peptide

*Other solvents from benzene to tetrahydrofuran, dimethylsulfoxide and water do not cause a third type of spectrum.

Forum Discussion Figure 28: 100 MHz NMR spectra of actinomycin D (IIa; A-conformation of the peptide rings) and of the α,β-isomeric na,*enantio*-actinomycins D (IIc; ratio 1:1).

group still exerts a preformative influence on the adjacent linear peptide (yield of cyclisation, NMR analysis of the α- and β-deuterio compounds[1]). Opening of *both* rings however (IIb) causes a strong conformational inhomogeneity as indicated by very broad-lined and uncharacteristic spectra.

In the well crystallized, but bacteriostatically inactive (*na,enantio*)-*actinomycins D* (IIc) containing two enantiomer peptide lactones a stabilizing interaction between the rings is lacking. The broad-lined and very complex NMR spectrum (Figure 28; *N*-methyl region (!); no association effects) differs strongly from that of IIa and also contains characteristic signals of the *C*-conformation of the free peptide lactone I. This--contrary to IIa--nonuniform behavior of the two peptide groups is a good proof, that a mere clamping of the *cyclo*peptides is not sufficient for a conformational stabilization; this needs a marked interannular interaction, for instance by hydrogen bridges.

Some interesting chemical and optical properties of the IIc-molecules and the problem of a slow rotation of the peptide groups are under investigation.

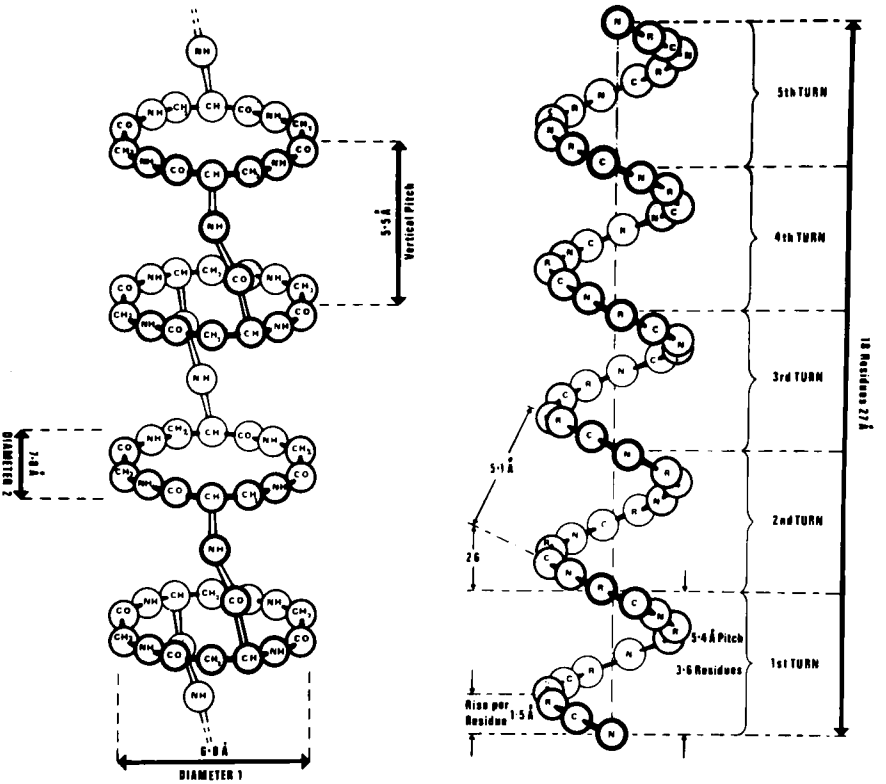
CHEMISTRY AND BIOLOGY OF PEPTIDES

SOME STUDIES RELATING TO THE SYNTHESIS OF CYLINDRICAL PEPTIDES

C. H. Hassall. Roche Products Ltd., Welwyn Garden City, Herts, United Kingdom

I WOULD LIKE TO SAY SOMETHING, briefly, about some work which is still very much in progress. It relates to an attempt to synthesize particular cylindrical peptides. These compounds are members of a family in which cyclic peptides are linked in such a fashion that hydrogen bonding between the individual rings contributes towards producing a cylindrical form. Figure 29 illustrates this concept for 14-membered oligopeptide rings and compares the dimensions for this case with those of a protein α-helix. The reason for the choice of the 14-membered ring system is further clarified by the consideration of Figure 30. The design was based on the conformation assigned by Dale to cyclotetradecane. If this representation in Figure 30 is considered in detail, it will be observed that the NH-function in one ring is attached to a carbon atom on the 14-membered ring below. As a result, a conformation which is highly favored for inter-annular hydrogen bonding is obtained.

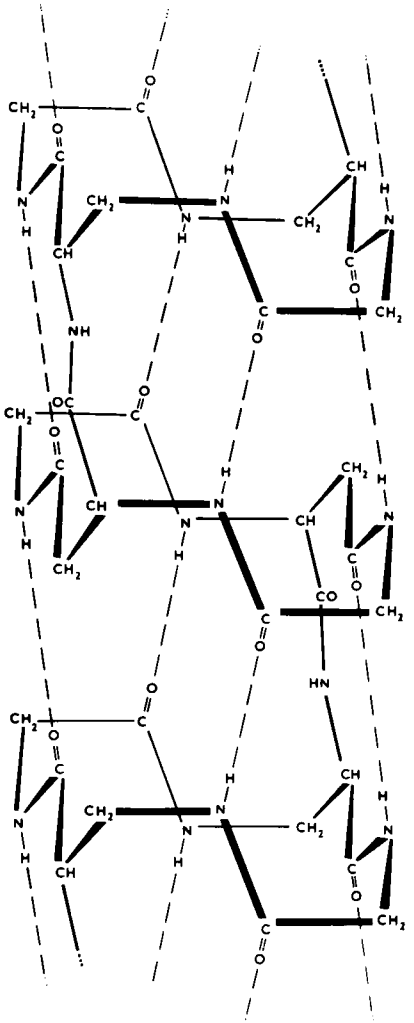
In order to obtain some experimental evidence of the conformations of such 14-membered cyclic peptides, a detailed investigation of the natural product serratamolide and related synthetic cyclodepsipeptides has been undertaken.[1] In summary, the proton NMR evidence indicates a remarkably rigid conformation--there is no change over a temperature range of approximately 250°--but there are some differences from compound to compound depending on the chirality at the different centers of asymmetry. As a general rule it appears that a pseudo-equatorial arrangement of side chains is favored, and the conformation of the ring is influenced by this.



Forum Discussion Figure 29: Dimensions of cylindrical peptides consisting of 14-membered cyclic peptide units linked to one another by peptide bonds in comparison with dimensions of the α-helix.

The synthesis of typical 14-membered cyclic oligopeptides[2] is illustrated in Schemes I and II. The synthesis of the linear tetrapeptides utilizes conventional stages. The ring closure step proceeds in quite good yields (approximately 60%) through the use of *o*-phenylene chlorophosphite reagent.

The compound represented on the right-hand side of Figure 31 has been prepared in 40% yield[3] by azide coupling of the individual cyclic peptides. The representations of conformations follows from proton NMR studies



Forum Discussion Figure 30: Projected hydrogen bond formation in cylindrical peptides consisting of 14-membered ring units

of serratamolide and analogues. Unfortunately, this product is not crystalline. The molecular structure cannot therefore, be investigated by X-ray diffraction methods. However, other combinations of such cyclic peptides with different side chains are in preparation. It is intended to pursue further studies to provide direct evidence of the molecular structures of these compounds. Moreover, particular compounds are designed to allow the investigation

of neighboring-group interactions resulting from the propinquity of the functions attached to separate 14-membered rings.

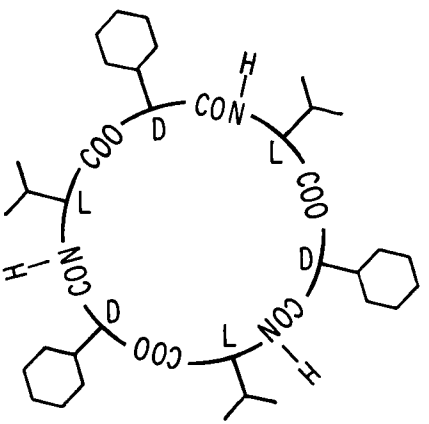
CONFORMATIONAL ANALYSIS OF A CYCLIC HEXADEPSIPEPTIDE, CYCLO-TRI[D-HEXAHYDROMANDELYL-L-VALYL]

Alvin Steinfeld, Ugo Lepore, Murray Goodman. Department of Chemistry, University of California, San Diego, La Jolla, California 92037.

Alan Tonelli. Bell Telephone Laboratories, Murray Hill, New Jersey

WE WOULD LIKE VERY BRIEFLY to describe our work on a cyclic hexadepsipeptide composed of alternating D-hexahydromandelic acid and L-valine residues (Figure 32), whose synthesis[1,2] was carried out in our laboratories. NMR spectra for the compound were measured on a 220 MHz apparatus in the following solvents: cyclohexane-d_{12}, benzene-d_6, CCl_4, $CDCl_3$, *p*-dioxane-d_8: CD_3OD (2:1), trifluoroacetic acid (TFA), and TFA-acetonitrile-d_3.



Forum Discussion Figure 32: Cyclo-tri-(D-hexahydromandelyl-L-valyl) a cyclic hexadepsipeptide

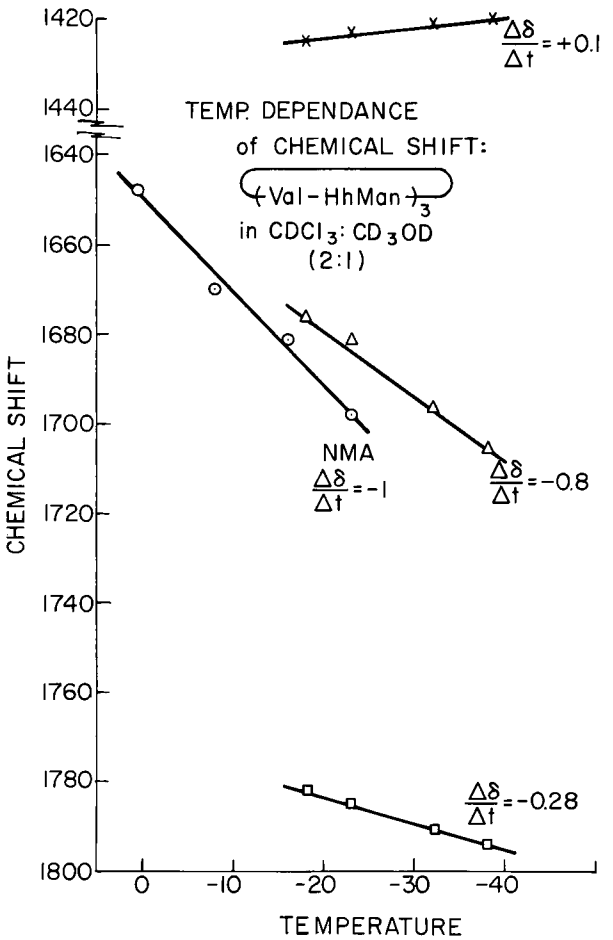
In TFA a single NH peak is observed for all the valine residues. Likewise, all the α-CH protons from hexahydromandelic acid occur as a singlet, separate from the singlet observed for the α-CH protons from the valine residues. These results led us to conclude that the cyclic hexadepsipeptide assumes a symmetrical conformation in TFA. Essentially identical results were obtained using acetonitrile as a solvent.

For less polar solvents, the NH and α-CH protons of each residue show absorptions at different chemical shifts. The NH protons appear as two widely separated doublets with a broad singlet between them. For the α-CH regions, the hexahydromandelic acid residues can be seen as two or three separate singlets while the valine residues exhibit two triplets and a singlet.

In all such cases, the coupling constants for the NH doublets vary between 9.5 and 10.0 Hz, while the signal appearing as a broad singlet has a coupling constant of less than 2.0 Hz. We were able to make an excellent correlation between the respective NH and α-CH peaks of the valine residues in $CDCl_3$ (at -36°C) because of the clear and accurate coupling constants we could measure. One α-CH has a coupling constant of less than 2 Hz and is associated with the midfield NH showing the same coupling constant. A perfectly symmetrical triplet for another of the valine α-CH residues has a coupling constant of 10.0 Hz while links this absorption to the highfield valine N-H showing the same coupling constant. The remaining α-CH triplet can be correlated in the same manner with the downfield NH absorption.

The change in chemical shift of the NH protons as a function of temperature has been observed in cyclohexane, $CDCl_3$: CD_3OD (2:1) (with N-methylacetamide (NMA) as an internal standard), and $CDCl_3$ (with NMA internal standard). The spectra in these solvents indicate that the high and low field NH protons (doublets, J = 9.5-10.0 Hz) have low temperature coefficients relative to NMA and to the third midfield NH proton (J < 2.0 Hz). The midfield NH proton and NMA show nearly the same temperature coefficient. Our results can be seen in Figure 33.

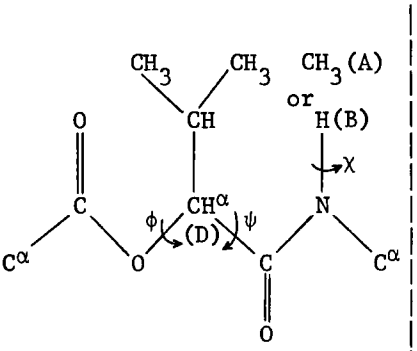
These results indicate that two of the valine NH protons are involved in intramolecular hydrogen bonds or are hidden from the solvent. It is interesting to note that the high field NH shows a positive temperature coefficient with decreasing temperature. This unusual behavior may result from the placement of this NH in an environment where it is hidden from the solvent but not hydrogen bonded.



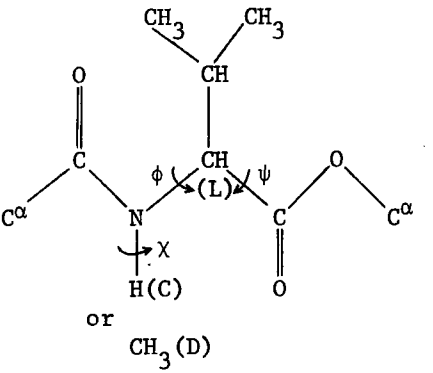
Forum Discussion Figure 33: Temperature dependence of chemical shift for $(Val\text{-}HhMan)_3$ in $CDCl_3$: CD_3OD (2:1). The curves are shown for the NH protons as referred to N-methylacetamide (NMA).

Any structure which we deduce must show that one of the valine N-H groups is exposed to the solvent. In this way, its behavior is expected to parallel the N-H group temperature dependence for N-methylacetamide.

Conformational energy $V(\phi,\psi,\chi)$ maps were calculated for the following *trans* peptide and ester bond fragments:



Map A + B



Map C + D

The potential functions, bond lengths, valence angles, 6-12 nonbonded potential constants, torsional barrier heights and partial atomic charges employed in these energy calculations were taken from Brant, Miller and Flory[3] and Brant, Tonelli and Flory.[4] The 6-12 potential constant $C_{N,O}$ and $A_{N,O}$ $\left(-\frac{C_{N,O}}{r_{N,O}^{6}}+\frac{A_{N,O}}{r_{N,O}^{12}}\right)$ appropriate to the nonbonded van der Waals interactions between the amide nitrogen and the ester oxygen atoms were evaluated in the usual manner.[3,4] Backbone rotations ϕ and ψ were varied in 10 degree increments, while rotation χ about the C^{α} - C^{β} bond was restricted to the three staggered conformations.

The resulting conformational energy maps agree closely with those calculated by Ovchinnikov *et al.*[5] in their studies of the solution conformations of enniatin B, valinomycin and their complexes with metal ions.

In the search for low energy cyclic conformations of the cyclic depsipeptide (Figure 32) only those conformations $(\phi,\psi)_{amide(L)}$ and $(\phi,\psi)_{ester(D)}$ that lie within the 5.0 kcal/mol energy contour of Maps B + C are considered.

Several attempts were made in this search, and in the final one each of the amide bonds was kept planar and *trans* while the ester bonds were allowed to adopt both the *cis* and the *trans* conformations.

Of the cyclic conformations generated in this search, one was found to be most consistent with the NMR data. This conformation [$(\omega,\phi,\psi)_{A1}$ = 0°, 240°, 240°; $(\omega,\phi,\psi)_{E2}$ = 180°, 250°, 0-30°; $(\omega,\phi,\psi)_{A3}$ = 0°, 120°, 0°; $(\omega,\phi,\psi)_{E4}$ = 0°, 280°, 120°; $(\omega,\phi,\psi)_{A5}$ = 0°, 240°, 240°; and $(\omega,\phi,\psi)_{E6}$ = 180°, 260°, 30°] possesses two intramolecularly hydrogen-bonded amide protons, $(N\text{-}H)_{A1}$ and $_{A5}$. Both amide protons belong to peptide residues with large $J_{N_\alpha}(\phi = 240°, \phi = 0°)$ and both are hydrogen-bonded to the C=O group of the amide 3 residue. One of these hydrogen bonds [$(N\text{-}HO_{A5}\text{---}(O{=}C)_{A3}$] is a seven-membered hydrogen bond of the type discussed by Bystrov *et al.*[6] As noted previously,[7,8] this kind of hydrogen bond should be rather weak because of its marked nonplanar nature. However, as can be seen in the photograph of the proposed cyclic depsipeptide conformation, $N\text{-}H_{A5}$ is partially internally buried (Figure 34). Thus, even if its hydrogen bond to $(C{=}O)_{A3}$ is weak, one might still expect[9-14] its chemical shift to be nearly temperature independent. Figure 35 shows the other side of the molecule. As we predicted from the temperature dependence studies, one of the valyn N-H groups is completely exposed to the solvent.

The A1 and A5 residues both possess ϕ = 240° or ϕ' = 0° [($J_{N\alpha}$ = 8.0 Hz (calc), 9.5 Hz (exp.)] in the proposed solution conformation of the depsipeptide, *i.e.*, the amide and α-protons in both residues are *cis* to each other.

The NMR spectra of the cyclic hexadepsipeptide reveal large coupling constants $J_{\alpha-\beta}$ = 6.5-9.5 Hz between the α and β protons in each residue. If we assume only the staggered conformations of the side chain are allowed, this observation leads to the conclusion[15] that the three rotational states χ = 60, 180 and 300° about the C^α -C^β bond are appreciably populated.

Moreover, we find no side chain-side chain or side chain-backbone steric interactions which would prevent the side chain in any of the six residues from adopting any of the three staggered conformations about the C^α -C^β bonds.

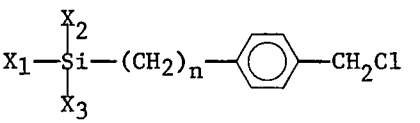
CHEMISTRY AND BIOLOGY OF PEPTIDES

PELLICULAR SILICONE RESINS AS SOLID SUPPORTS FOR PEPTIDE SYNTHESIS

Wolfgang Parr, Karel Grohmann. Chemistry Department, University of Houston, Houston, Texas 77004

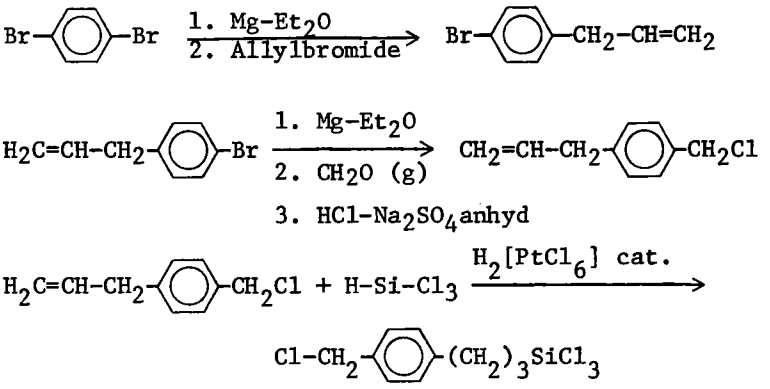
IT HAS BEEN SHOWN THAT silicone polymers can be successfully bound to the surface of silicaceous materials through chemically stable Si-O-Si-C bonds.[1-3] Because of their reactivity modified halosilanes were chosen as monomers in these investigations. The growing peptide chain could be attached to the silicone polymer through formation of a benzyl ester linkage because its behavior during the course of synthesis is well established. The reactive monomers used for the preparation of chemically bonded layers were generally of the type:



n = 0,2,3,4
X_1 = Cl
X_2,X_3 = Cl or Methyl

There are two general methods for the preparation of the desired monomers. The first one consists of a reaction of a suitably substituted Grignard reagent with tetrachlorosilane. We have used this reaction for the preparation of *p*-tolylmagnesium bromide with silicon tetrachloride.[4] The obtained *p*-tolyltrichlorosilane was then brominated by *N*-bromosuccinimide in CCl_4 solution at reflux. Excess succinimide and solvents were removed and the crude product was distilled twice *in vacuo*. The structure and purity of *p*-bromomethylphenyltrichlorosilane [I] was determined by NMR spectroscopy. Higher homologs were prepared by the addition of suitably substituted olefins

to trichlorosilane.[5] This reaction is catalyzed by hexachloroplatinic acid. The suitable starting olefin was prepared by the sequence of following reactions:[6]



[II]

The NMR data confirmed the presence of one isomer only, formed by terminal addition of $SiCl_3$ group.

These silicone monomers were bonded to porous silica beads (Porasil E, average pore diameter 800-1500 Å, surface area 10-20 m^2/g, manufactured by Waters Associates) or porous glass beads (Bio-Glass, pore size 1000, 1500, or 2500 Å, surface area undisclosed, manufactured by Bio-Rad Laboratories). The beads were first refluxed overnight with concentrated hydrochloric acid in order to remove absorbed cations, then washed successively with distilled water and methanol, dried under vacuum and then heated overnight to 105°C.

Individual batches of beads were then stirred or shaken overnight with 1% solution of monomers in benzene. Excess monomers were removed by repetitive washing with dry benzene. Hydrolysis of remaining Si-Cl groups was achieved by washing the beads either with water-ethanol-benzene (5:45:50) or with ethanol-water (1:1). After drying, the beads were polymerized at 105°C for 24 hours.

The silanized beads were washed with ethanol and benzene in order to remove absorbed impurities. The capacity of the beads was in the range of 0.03-0.1 mequiv Cl or Br/g as determined by modified Volhard analysis. These values correspond very well to the capacity values calculated for monomolecular layers. The absorption of dyes have shown, however, that the beads are coated quite unevenly. Also, the

presence of very fine particles after each manipulation step shows that particles break down easily, which leads to the losses of support.

Synthesis of Model Peptides

The first protected amino acids were esterified to the benzylic group by refluxing the glass beads with triethylammonium salt of Boc-amino acid in dioxane for 24-38 hr.[7] The beads were washed with dioxane, ethanol, benzene, and petroleum ether, then dried *in vacuo* and, in aliquots of beads, the Boc-group was cleaved. Chloride was titrated. The yields of attachment were quite variable (30-50%) and the extent of side reactions also varied to a considerable degree.

Two peptides had been synthesized by standard batch procedure.[8] In both cases, DCC coupling was used exclusively. The tetrapeptide H-Pro-Gly-Phe-Ala-OH was synthesized on the glass beads with the aryl group attached directly to the silicone atom [I]; 120 mg of crude product was obtained. Only 50% of the peptide was cleaved from the support with HBr in TFA, as determined by total hydrolysis of the remaining glass beads with 6*N* HCl and amino acid analysis. The second peptide H-$(Phe\text{-}Ala)_6$-OH was synthesized on glass beads silanized with monomer [II], in which the aryl group was separated from the silicon atom by three methylene groups. HBr cleavage was 90% complete in this case and 249 mg of crude product was obtained. This discrepancy is easily explained by the strong electron withdrawing effect of the SiO_3 group which destabilizes the cationic reaction intermediate.

The tetrapeptide was checked for purity by amino acid analysis (molar ratio Pro 0.95, Gly 1.00, Ala 1.00, Phe 1.05) and by thin-layer chromatography (tlc). None of the techniques revealed the presence of lower peptides which would be the result of incomplete reaction steps. The dodecapeptide was partially hydrolyzed by 12*N* HCl, the obtained amino acids and lower peptides were esterified, trifluoroacetylated and analyzed by GC-MS combination according to Bayer *et al.*[9] No dipeptides of the type Ala-Ala or Phe-Phe were detected, but this result can be considered only as semi-quantitative due to formation of not only dipeptides, but also free amino acids and higher peptides, where failure sequences could be hidden.

In the last experiment we have tested the suitability of silicone supports for column procedures. All steps starting from attachment of the second amino acid were

carried out by pumping reagents and solvents through a column packed with silanized glass beads.

Bio-Glass 1500 silanized with [II] (capacity 0.108 mequiv Cl/g) was reacted with excess of triethylammonium salt of Boc-Tyr(Bzl) as described previously. A chromatographic column (65 x 0.9 cm) was filled with 30 g of aminoacyl glass beads. A second column served as the solvent reservoir. All operations, but coupling, were performed by pushing solvents or reactants with nitrogen through the column. The effluent was collected and tested for completeness of washing steps. *P*-Nitrophenyl-ester coupling was used exclusively. Solutions of Boc-amino acid-ONp were recycled through the system with a Beckman Accu-Flow pump. The peptide synthesized was H-Gln-Gln-Gly-Gly-Tyr(Bzl)-NH_2. The coupling of both Boc-Gly-ONp esters was performed in chloroform and the speed of reaction was followed by measuring adsorbance at 315 nm. The measurements showed that the reaction was practically complete after 6 hours. No significant difference in coupling rates of the second and third glycine was noted. The obtained UV values were checked by the reaction of the unreacted NH_2 groups with Pyridine-HCl and subsequent titration of chloride as described by Dorman.[10]

The peptide was cleaved from the resin by transesterification with methanol-triethylamine for 24 hours; the cleavage was monitored by measuring UV adsorbance at 280 mm; 530 mg of the crude peptide was obtained. The collected peptide was purified by gel permeation chromatography on Sephadex LH-20. Methanol was used as the eluant. The purification step on Sephadex LH-20 revealed the presence of small amounts of lower peptides. This finding was confirmed by amino acid analysis and tlc of the crude peptide. The purified pentapeptide was amidated by ammonolysis in saturated solution of ammonia in the mixture DMF-methanol (2:1) for three days at room temperature. The Boc-group was then cleaved by 1 *N* HCl in acetic acid for 30 minutes. Deprotection of Tyr(Bzl) was carried out by catalytic hydrogenation over 10% Pd-charcoal H_2 pressure 55 psi, reaction time 12 hr.

The deprotected peptide was dissolved in methanol-water (1:2) and placed into a refrigerator. The pentapeptide precipitated out of solution in the form of a gel. Upon drying the gel *in vacuo* a white powder formed. The peptide was purified by gel permeation chromatography on Sephadex G-15 column (43 x 2.5 cm) with methanol-water (1:2) used as an eluant. The peptide was eluted as a single peak. Tlc on silica gel in two solvent systems [solvent I,

methanol; solvent II, *n*-butanol-water-pyridine-acetic acid (15:12:10:3)] also showed single spots.

The presented results show that peptides can be successfully synthesized on this kind of support. More precise and sensitive analytical techniques will have to be developed, however, before the advantages and disadvantages of these supports can be clarified.

CHEMISTRY AND BIOLOGY OF PEPTIDES

GRAFT COPOLYMERS AS INSOLUBLE SUPPORTS IN PEPTIDE SYNTHESIS

Geoffrey W. Tregear. Endocrine Unit, Massachusetts General Hospital, and Department of Medicine, Harvard Medical School, Boston, Massachusetts

GRAFT COPOLYMERIZATION[1] affords an opportunity of obtaining a 0% crosslinked, physically stable polystyrene resin with improved properties for use in solid-phase peptide synthesis. The polystyrene chains can be insolubilized without crosslinking by anchoring them at one end to an inert, insoluble core resin such as Teflon or Kel F (see Figure 1). This may be accomplished experimentally by irradiating the core polymer with ionizing radiation such as γ or x-rays, in the absence of air and exposing the irradiated polymer to styrene monomer. The irradiation produces free radical sites throughout the bulk of the core polymer but with resins

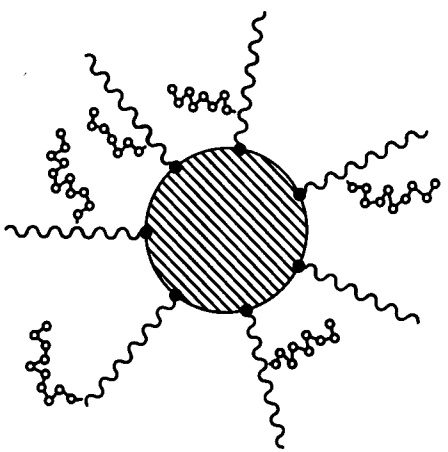

Figure 1: Diagrammatic representation of a graft copolymer resin for use in solid-phase peptide synthesis. The polystyrene chains which provide the point of attachment for the growing peptide chain are insolubilized by grafting to an inert core resin.

such as Teflon or Kel F which are not swollen by solvents or monomer the styrene only "sees" the free radicals at the surface and polymerization of the grafted side chains occurs only at these points. By the appropriate selection of experimental conditions it is possible to achieve surface grafting with minimal crosslinking. The number of grafted side chains is determined by the number of free radical sites which is a function of the total dose of radiation. The length of the grafted chains is a function of the polymerization rate and is controlled by the dose-rate and experimental conditions such as temperature of irradiation and presence of solvent or chain terminating reagents.

A unique advantage of this system is that the backbone polymer can be prefabricated as film, discs, pellets or small diameter beads and this physical form is retained throughout the grafting procedure and the subsequent chloromethylation step.

A particularly useful graft copolymer for use in peptide synthesis consists of a core of small diameter beads of Kel F with a 10% by weight surface graft of polystyrene. We have been using this type of resin routinely in our laboratory and have been particularly impressed with its physical characteristics. Being 90% Kel F the resin displays essentially the properties of the core polymer. It does not swell appreciably, it is very dense and sinks rapidly in all solvents and does not stick to glassware.

To compare the performance of the grafted resin with the conventional 1% crosslinked polystyrene the two resins were mixed together in the same reaction vessel. Both resins were chosen to have the same chloromethyl substitution of the polystyrene chains (17%). At any point during the synthesis the two resins could be separated by the addition of methylene chloride. The crosslinked polystyrene resin floats while the graft copolymer resin being very dense, sinks. The separation is rapid and complete.

As a test synthesis, the amino terminal dodecapeptide sequence H-Ala-Val-Ser-Glu-Ile-Gln-Phe-Met-His-Asn-Leu-Gly-OH of bovine parathyroid hormone[2] was prepared in the Beckman-990 Peptide Synthesizer. The progress of the synthesis was monitored by the qualitative ninhydrin test of Kaiser *et al.*[3] Quantitative data on the extent of reaction was obtained using the Beckman-890C Sequencer[4] (see Figure 2). Both resins were surprisingly similar in their reaction characteristics. In general the carbodiimide couplings were complete on both resins after 5 to 10 min reaction time and the active ester couplings after 2 to 4

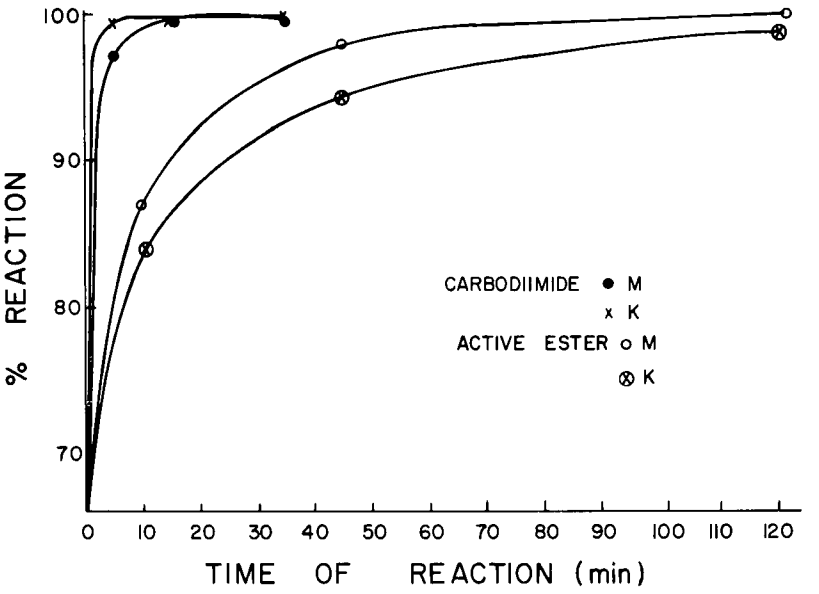

Figure 2: Rate of coupling reaction for the graft copolymer resin (K) and the 1% crosslinked polystyrene resin (M) during the synthesis of sequence 1-12 of bovine parathyroid hormone. The carbodiimide coupling step was Phe to Met and the active ester step Asn to Leu. The extent of reaction was determined from Automated Edman Sequence Data.[4]

hr. Inefficient couplings requiring a repeat reaction or change in solvent occurred at the same sequence positions with both resins (Ile to Gln and Glu to Ile).

The yield of dodecapeptide after preliminary purification by gel filtration and based on the original amount of chloromethyl groups available on the resin was 30.5% for the 1% crosslinked resin and 25.8% for the graft resin. The purity of the peptides obtained from each resin was assessed by amino acid analysis, sequence determination and thin layer chromatography. In all these systems the products were indistinguishable.

The similarity in reaction characteristics and performance combined with the ease of separation of the two

resins has opened up an interesting application whereby two different peptides may be synthesized at the one time under the same experimental conditions. For example in the study of structure-activity relations at the carboxyl terminus of a peptide it is possible to use the graft resin esterified to one particular amino acid and the crosslinked polystyrene resin esterfied to a different amino acid. The remainder of the peptide chain can then be assembled under the same experimental conditions. The biological importance of a carboxyl terminal amide in a peptide may also be investigated by using one of the resins as the benzhydrylamine derivative and the other resin in the chloromethyl form.

Although the current experiments have demonstrated that the graft copolymer resins are comparable to but not significantly better than the conventional 1% crosslinked resins it should be pointed out that the graft resins offer a considerably flexibility in design which has not yet been fully exploited and which should lead to greatly improved resin properties. The optimal physical characteristics of the core polymer and the effects of altering the number and length of the grafted polystyrene chains have not yet been fully evaluated. An improved spatial arrangement of the side chains should also be possible by block copolymerizing the grafted styrene with other monomers to obtain a more controlled distribution of styrene units and to render the grafted side chains comparable in polarity with the growing peptide chain.

Acknowledgment

The graft copolymer resin described in this report was synthesized by Dr. H. Battaerd, Mr. G. Lang and Mr. M. Scandrett at the Central Research Laboratories, Imperial Chemical Industries (Australia) Ltd. The chloromethylated 1% crosslinked polystyrene resin was kindly provided by Dr. B. Gisin of the Rockefeller University, New York.

CHEMISTRY AND BIOLOGY OF PEPTIDES

SOLID-PHASE SYNTHESIS OF PROTECTED PEPTIDE FRAGMENTS

Su-Sun Wang. Chemical Research Department, Hoffmann-La Roche Inc., Nutley, New Jersey, 07110

THE PROBLEM OF DECREASING purity in the chain elongation process using the solid-phase technique[1] may be approximated by the binomial distribution law. The relationships between the expected purity of the product, the chain length of target peptide and the average coupling efficiency can be illustrated in Figure 1. It is apparent that near 100% efficiency in each step and every cycle is required when a large polypeptide is to be synthesized. The preparation of protected fragments by the solid phase technique followed by fragment condensation might serve as an alternative. In the following, the preparation and application of two resins suitable for the synthesis of protected fragments is described.

Preparation of the Resins

Merrifield resin (chloromethylated copolystyrene-2% divinylbenzene) was reacted with $CH_3OCO\text{-}C_6H_4\text{-}OH$ and $NaOCH_3$ to form $CH_3OCO\text{-}C_6H_4\text{-}OCH_2\text{-}C_6H_4\text{-}$Resin. Reduction with $LiAlH_4$ gave *p*-alkoxybenzyl alcohol resin (I) ($HOCH_2\text{-}C_6H_4\text{-}OCH_2\text{-}C_6H_4\text{-}$Resin). The same resin can also be prepared from Merrifield resin and $HOCH_2\text{-}C_6H_4\text{-}OH$ plus $NaOCH_3$. Acylation of I with phenyl chloroformate gave the phenyl carbonate resin which on hydrazinolysis yielded *p*-alkoxybenzyloxycarbonylhydrazide resin (II) ($H_2NNH\text{-}CO\text{-}OCH_2\text{-}C_6H_4\text{-}OCH_2\text{-}C_6H_4\text{-}$Resin).

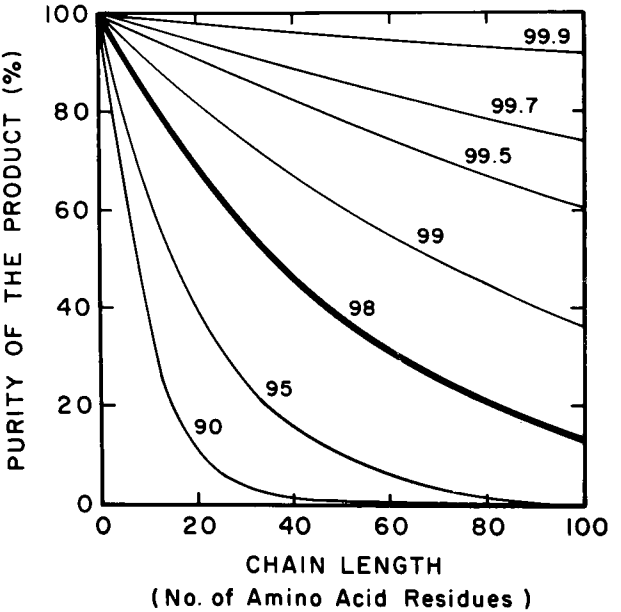

Figure 1: Relationship between average coupling efficiency and purity of products prepared by the solid-phase method.

Attachment of Amino Acids to the Resins

2-(*p*-Biphenylyl)isopropyloxycarbonylamino acids (Bpoc-amino acids) were attached to I using dicyclohexylcarbodiimide (DCC) (1 equiv. of pyridine as catalyst) or by the *p*-nitrophenyl ester method (10 equiv. of imidazole as catalyst). The unreacted hydroxyl group on the Bpoc-amino acyl resin was then blocked by benzoylation (benzoyl chloride and pyridine). No racemization was detected during the esterification process. Bpoc-amino acids were attached to resin II efficiently with the DCC method. Substitutions on I and II were normally 0.3-0.6 mmol/g.

Application of the Resins

Bpoc-Phe-Resin I was deprotected with 0.5% trifluoroacetic acid (TFA), neutralized and coupled with Bpoc-L-Val, Bpoc-L-Leu and Z-L-Leu to give Z-Leu-Leu-Val-Phe-Resin I

by a procedure similar to that described before.[2] Treatment with 50% TFA in CH_2Cl_2 (30 min) liberated the peptide from the resin. Pure crystalline Z-Leu-Leu-Val-Phe (mp 216-219°) was isolated in an overall yield of 68% calculated from the phenylalanine content of Bpoc-Phe-Resin I. During the synthesis, a four-fold excess of amino acid derivatives and coupling agent (DCC) was used in each cycle. The product was converted to its methyl ester (Z-Leu-Leu-Val-Phe-OCH_3; mp 204-206°) by dilute methanolic HCl.

Bpoc-Gly-ONp was reacted with I in the presence of imidazole to give Bpoc-Gly-Resin I. Solid-phase synthesis with Bpoc-L-Phe, Bpoc-L-Phe and Z-L-Lys(Z) gave Z-Lys(Z)-Phe-Phe-Gly-Resin I. Cleavage with 50% TFA (30 min) afforded crystalline Z-Lys(Z)-Phe-Phe-Gly (mp 220-222°) in 60% overall yield. This fragment was condensed with a dipeptide methyl ester (Leu-Met-OCH_3·HCl) by the DCC method. The product, hexapeptide ester Z-Lys(Z)-Phe-Phe-Gly-Leu-Met-OCH_3 (mp 180-184°) upon ammonolysis yielded the crystalline hexapeptide amide Z-Lys(Z)-Phe-Phe-Gly-Leu-Met-NH_2 (mp 238-242°). The carbobenzoxy groups were removed by hot TFA (80°, 3 hr) in the presence of anisole and mercaptoethanol. The crude peptide was purified by counter-current distribution followed by gel filtration. The desired compound Lys-Phe-Phe-Gly-Leu-Met-NH_2 was obtained as an amorphous white solid, which was homogeneous on electrophoresis and thin layer chromatography. Acid hydrolysis and amino acid analysis gave the expected values.

Angiotensin II was also prepared using resin I. The protected octapeptide intermediate Z-Asp(OBzl)-Arg(NO_2)-Val-Tyr(Bzl)-Val-His(Tos)-Pro-Phe was obtained in a similar manner and the protecting groups were removed by treatment in liquid HF.[3] Purification by counter-current distribution and gel filtration gave an analytically pure produce (15% overall yield), which was homogeneous on electrophoresis and thin layer chromatography.

Resin II was utilized to prepare Z-Phe-Val-Ala-Leu-$HNNH_2$ by a procedure similar to that described previously.[2] The desired protected peptide hydrazide was obtained in 42% yield (mp 252-254°). It was found to be identical with a product prepared previously[2] by an alternate route.

Acknowledgments

The author thanks Dr. R. B. Merrifield for helpful discussions and Drs. G. Saucy and A. M. Felix for valuable suggestions and help with the manuscript.

AUTOMATIC MONITORING OF SOLID-PHASE PEPTIDE SYNTHESIS BY PERCHLORIC ACID TITRATION

K. Brunfeldt, D. Bucher, T. Christensen, P. Roepstorff, O. Schou, P. Villemoes. The Danish Institute of Protein Chemistry, affiliated to the Danish Academy of Technical Sciences, 33, Finsensvej, DK-2000, Copenhagen F, Denmark

I. Rubin. Department of Biochemistry A, University of Copenhagen. Copenhagen, Denmark

STEPWISE YIELDS NEAR 100% are required for the synthesis of long peptide chains.[1,2] A monitoring system for solid-phase synthesis must therefore possess a high degree of accuracy. A determination of the amount of liberated α-amino groups is a direct measure of the yield of protecting group cleavage. A direct determination of the coupling yield seems very difficult to achieve. Instead a measurement of the amount of residual α-amino groups after coupling may be used.

Titration of free α-amino groups with perchloric acid has been investigated in our laboratory.[3,4] The method is easily automated and sufficiently rapid (approx. 2 hr) to be used in automated peptide synthesis. The method is in principle non destructive and might be carried out without sampling. Our experience is, however, not extensive enough to ensure that damage in all cases (*e.g.* with Try- or Cys-containing peptides) can be avoided.

The titration is carried out in a mixture of methylene chloride and acetic acid 1:1 (v/v) on the whole batch in the reactor. A circulation system ensures a continuous washing of the walls of the reactor. A glass electrode

---

*Present Address: Department of Biochemistry A, University of Copenhagen.

and a calomel electrode with secondary salt bridge (10% sat aq LiCl in HOAc) are used. Approximately 0.05 *N* $HClO_4$ in HOAc is used as titrant.

The high concn of HOAc shifts the equilibrium $R\text{-}NH_2$ + HOAc $\rightleftarrows$ $R\text{-}NH_3^+ + OA_c^-$ to the right, the so-called levelling effect.[5] Therefore, the acetate ions are titrated by the $HClO_4$; and we used the same endpoint irrespective of the N-terminal amino acid. The method is not specific for α-amino groups and other groups may be titrated.

Loss of peptide and blocking of amino groups will both result in decreases of titration values, and other analytical methods must be used in addition for a correct interpretation.

All operations are coded on punched tape and automatically carried out by the combined synthesizer titration equipment.[6] Treatments before and stirring during titration are controlled by the synthesizer's control unit. When the code is read for titration, an interface based on sequential logic controls the titration equipment, consisting of a titrator, autoburette, stripprinter, and recorder. The titration is controlled by the titrator. The variations of the potential against time are recorded and serve as a control for proper electrode function as well as for demonstration of the course of the titration. When a titration is finished the total volume of added titrant is printed out and the interface signals to the synthesizer's control unit to read the next and all fol following codes.

The accuracy of titration is *ca.* ± 0,01 mequiv (single expt at 1 mequiv amine) and *ca.* ± 0,004 mequiv (at 0.1 mequiv amine). An increase in accuracy by optimizing the procedure seems possible. The technique is useful. We have thus demonstrated the presence of amino-group-blocking impurities in methylene chloride by repeated titration of an alanyl-resin.[7] In the repetitive solid-phase procedure even minute artefacts in each step may accumulate and thus significantly reduce the final yield. Therefore, purity of solvents and reagents is of a similar importance as in automated Edman degradation. Our automatic monitoring system may be used for checking solvents and reagents for solid-phase synthesis.

During an attempt to synthesize antamanide considerable amounts of dipeptide were cleaved from a H-Pro-Pro-O resin as diketopiperazine[6],* during the Et_3N treatment and subsequent washings. The titration values showed that the degree of diketopiperazine formation was prohibitive for

*Identified by mass spectrometry.

obtaining a reasonable yield of final product. Therefore the antamanid sequence H-Phe-Pro-Pro-Phe-Phe-Val-Pro-Pro-Ala-Phe-O-resin[8] was chosen as target. During this synthesis, the titrations after Boc-group cleavage strongly indicated irreversible blocking[6] since repetition of deblocking at the tetra- and pentapeptide stage did not change the titration value (see Figure 1). The difference

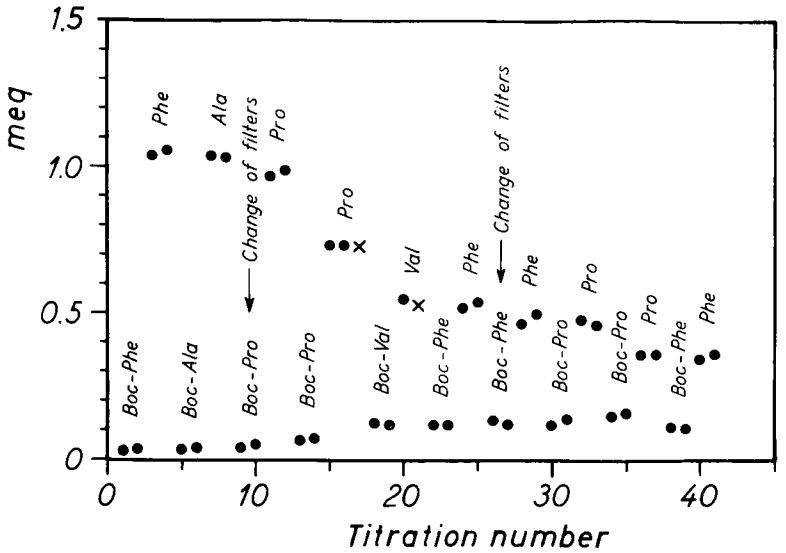

Figure 1: Titration values during the synthesis of a sequence of antamanid H-Phe-Pro-Pro-Phe-Phe-Val-Pro-Pro-Ala-Phe-O-resin. X indicates that the procedure for cleavage of the Boc-group was repeated before the titration. (By the courtesy of FEBS Letters.)

between the titration values with the Boc-group intact and after cleavage was used as a measure of amino acid incorporation at the respective step of the synthesis. The reasonable agreement between the titration values and amino acid analysis data, Table I, supported that a blocking had occurred, because a loss of peptide would have resulted in a pronounced discrepancy between the two tests. A loss of peptide would lead to a lower total yield but it would not influence the relative amino acid content of the product.

*Resin-bound product
†Cleaved crude product
#Ether precipitated product
**Cyclicized peptide (antamanid)
††Proline (amino acid analysis) corrected for concentration dependency of calibration factor

The amino acid analyses of the resin bound and cleaved product differed only slightly. Therefore, the hydrolysis of the resin bound peptide seems to have been reliable in this case. It was performed at 110° for 96 hr in a 1:1 mixture of 6 *N* HCl-glacial acetic acid in evacuated, sealed ampoules, followed by evaporation at reduced pressure and low temperature. The hydrolysis of the cleaved product was performed in 6 *N* HCl at 110° for 24 hr.

For the synthesis 2.2 g of Boc-Phe-O-resin with a substitution degree of 0.456 mequiv/g was used. For removal of the Boc-group *N* HCl-HOAc was used. The coupling reagent was DCC. The yield of the resin bound decapeptide

was determined by the titration to 20%. The crude cleaved product weighed 296 mg.

The titration results indicated the presence of tri-, tetra-, octa-, and decapeptide. The cleaved product was deuteroacetylated and permethylated.[9] Mass spectrometry then showed that the blocking was due to acetylation as the expected tri-, tetra-, and octapeptide were acetylated and only the decapeptide was deuteroacetylated. Furthermore, some acetylated heptapeptide was found. Minor amounts of failure sequences missing a proline or phenylalanine in positions where Pro-Pro or Phe-Phe was expected, were also detected. The acetylation was mainly due to acetic acid leaching out from all the teflon parts of the reaction system[6] into the coupling mixture.

The synthesis was twice repeated in an all glass system using 2.9 and 6.0 g of Boc-Phe-O-resin. The overall titration yields were 64% and 62% giving 1.06 and 2.20 g of crude products, respectively. Practically identical titration results were obtained in both experiments (Figure 2). No pronounced decrease was observed at any stage. The second titration values of proline at tetra- and nonapeptide stages were found to be lower than the first. A third titration was identical with the second. As in the first synthesis, Figure 1, an increase of the titration value after Boc-valine incorporation was observed. Repeated coupling did not improve this result, neither did succeeding couplings result in lower values. We are, at present, unable to explain these two observations. The latter may be due to steric hindrance prohibiting coupling but not protonization.

In the synthesis using 6 g Boc-Phe-O-resin the coupling with Boc-phenylalanine following valine led to a high titration value suggesting an incomplete coupling. A repeated coupling after change of the solutions lead to a value not different from the ones obtained before and after this coupling. From the crude cyclisized product a cycloundecapeptide containing 5 phenylalanine was isolated in addition to the expected cyclodecapeptide (antamanid). The unexpected high titration value thus must have been due to an undesirable partial deblocking of the amino group at the hexapeptide stage and not to an incomplete coupling with Boc-phenylalanine. The unexpected high titration value thus certainly revealed a human error.

The amino acid analysis of both resin bound final products and the amino acid compositions calculated from the titration values again agreed (Table I). Probably, the linear decrease in the titration values is partly due to blocking. It was not possible to verify this by mass spectrometry

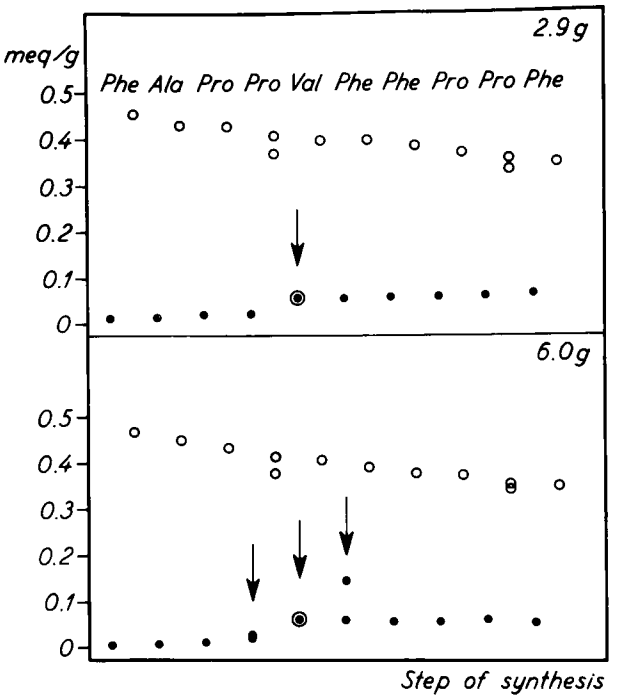

Figure 2: Titration values during synthesis of the sequence shown on the figure: 2,9 or 6,0 g of Boc-Phe-O-resin was used. Values are means of double determinations except the upper values of the Pro titrations in step 4 and 9, which are single determinations. meq, At the ordinate, refers to mequiv titrated per g of Boc-Phe-O-resin. •, Before Boc-group cleavage. O, After Boc-group cleavage. ↓, Repeated coupling. ⊙, Repeated double determination resulting in identical values.

because of the small amount of each component. Some acetylation seems likely to occur as acetic acid is difficult to wash out of the resin completely, as shown by utilizing ^{14}C-acetic acid. Furthermore, loss of peptide certainly did occur during these syntheses.[10,11]

The titration is not specific for α-amino groups. During the synthesis of renin substrate tetradecapeptide (1.8 g Boc-Ser(Bzl)-O-resin, 0.440 mequiv g) the titration values increased due to imidazole-*N* after N^{α}-Boc-N^{im}-Dnp-histidine incorporated. The titration value after Boc-group

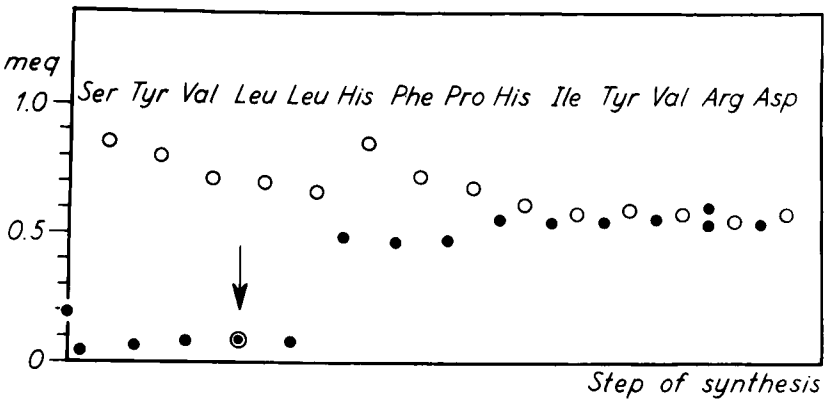

Figure 3: Titration values during synthesis of renin substrate tetradecapeptide. Values are means of double determinations except the first titration on Boc-Ser(Bzl)-O-resin and the upper one of Boc-Arg(NO_2)-peptide, which was the first of three determinations. Signatures as in Figure 2.

cleavage is the double of that obtained before cleavage (Figure 3). The titration value of the preceeding Boc-Leu was subtracted. The decrease from the first to the second titration of Boc-Ser(Bzl)-O-resin was due to removal of ionically bound Boc-Ser(Bzl)-OH.

Extensive acetylation nullified the yield after incorporation of the second histidine in the teflon containing reactor system. Mass spectrometry confirmed the presence of acetylated C-terminal penta-, hexa-, hepta-, and octapeptides. The decrease in titration values at the di-, and tripeptide stage was mainly due to formation of Tyr(Bzl)-Ser(Bzl) diketopiperazine which was identified by mass spectrometry and use of ^{14}C-tyrosine. The diketopiperazine formation begins during the triethyl amine treatment and lasts throughout the end of the following Boc-valine coupling. C-Terminal diketopiperazine formation has also been observed in other laboratories.[12-14]

A modification of the titration procedure in which the present titration medium is replaced by halogenated alkanes containing a quarternary ammonium salt as carrier electrolyte, is under investigation.

CHEMISTRY AND BIOLOGY OF PEPTIDES

IMPROVED PROTECTING GROUPS FOR SOLID-PHASE PEPTIDE SYNTHESIS

Bruce W. Erickson, R. B. Merrifield. The Rockefeller University, New York, New York 10021

THE SUCCESSFUL SYNTHESIS of pure peptides by the solid-phase method requires a careful choice of protecting groups. When the Boc group is used for temporary protection of the α-amino groups, side chain protecting groups must be stable during acidolysis of the Boc groups and yet be removed by a stronger acid at the end of the synthesis.

We have established the relative stability of the benzylic protecting groups toward acid by determining the apparent first-order rate constants for the deprotection of seven side chain-protected amino acids with 50% (v/v) trifluoroacetic acid in dichloromethane [50% TFA] at 20° (Table I). The

Table I

Apparent First-order Loss of Benzylic Side Chain Protecting Groups in 50% TFA -- CH_2Cl_2 at 20°

Protected amino acid	k_1 $(10^{-4}\ hr^{-1})$	*Relative rate*
Thr(Bzl)	2.5	[1.0]
Glu(OBzl)	3	1
Asp(OBzl)	3	1
Ser(Bzl)	3.9	1.5
Cys(4-CH_3OBzl)	29	12
Lys(Z)	142	57
Tyr(Bzl)	181	73

relative amounts of the free and the protected amino acid were measured on a 13-cm column of sulfonated polystyrene eluted with pH 7 buffer at a temperature between 56 and 96°.

Thr(Bzl) is sufficiently stable to survive extensive treatment with 50% TFA during solid-phase synthesis, since exposure to 50% TFA for 40 hr caused only 1% loss of the benzyl group. The stability of Glu(OBzl), Asp(OBzl), and Ser(Bzl) toward 50% TFA is essentially the same as that of Thr(Bzl). Cys(4-CH_3OBzl) was deprotected 12 times faster than Thr(Bzl), which suggests that the 4-methoxybenzyl group may not provide sufficient protection for cysteine residues during the synthesis of large peptides.

Protection of tyrosine as the benzyl ether is not recommended for two reasons. Not only was Tyr(Bzl) deprotected 73 times faster than Thr(Bzl), but this reaction furnished a mixture of 63% tyrosine and 37% 3-benzyltyrosine.[1] The ratio of these products was constant for 100 hr, during which 85% of the Tyr(Bzl) reacted. Since essentially the same results were obtained when 100 equivalents of anisole were present per equivalent of Tyr(Bzl), the 3-benzyltyrosine is probably formed by an intramolecular rearrangement.[2-4]

In contrast, *O*-(2,6-dichlorobenzyl)tyrosine, which was stable to 50% TFA for at least 350 hr at 20°, is deprotected at least 4000 times slower than Tyr(Bzl) and at least 60 times slower than Thr(Bzl). Both Tyr(Bzl) and Tyr(2,6-Cl_2Bzl) were completely deprotected on treatment with HF for 10 min at 0° to provide a mixture of 60% tyrosine and about 40% of the respective 3-benzylated derivative. After exposure to 50% HF--anisole for 10 min at 0°, 13% of the Tyr(Bzl) was converted into 3-benzyltyrosine but only 4% of Tyr(2,6-Cl_2Bzl) was isomerized to the ring-alkylated derivative. Protection of the phenolic hydroxyl group of tyrosine as the 2,6-dichlorobenzyl ether is an improvement over use of the benzyl ether, but it does not solve the problem of intramolecular benzylation of the phenolic ring.

Loss of the N^{ε}-protecting group from a lysine residue during solid-phase synthesis generates a free ε-amino group that can couple subsequently with an activated amino acid to form a branched peptide. In order to examine the distribution of branched peptides, we have synthesized decalysylvaline using Z to protect the ε-amino group of lysine. Boc-valyl-oxymethyl-polystyrene resin was deprotected for 1 hr with 50% TFA, neutralized with diisopropylethylamine, coupled for 1 hour with three equivalents each of Boc-Lys(Z) and DCC, and again neutralized and coupled. These excessive deprotection conditions were purposely used to accentuate the formation of branched peptides. Repetition of this

cycle nine times and treatment of the resin with HF and anisole for 1 hr at 25° furnished a crude peptide mixture that was analyzed[5-7] on a 50-cm column of carboxymethylcellulose using a sodium chloride gradient. After elution of decalysyl-valine, a series of peaks due to branched peptides containing 11-19 lysine residues was observed.

To a first approximation, each of the branched peptides was formed as a result of the loss of one Z group somewhere along the polylysyl-valine chain during a certain deprotection step. The peptide containing 18 lysine residues, for example, arose by loss of either Z group from a fully protected lysyl-lysyl-valine chain. Thus the mole percent found for each branched peptide provides an estimate of the rate at which the Z groups are lost during removal of the Boc groups with 50% TFA. The average loss of Z groups from the protected peptide resin was 0.8% per hour per Lys(Z) residue. This result agrees well with the loss of 1.4% per hour observed for the deprotection of Lys(Z) in solution. This agreement suggests that the rates of deprotection of side chain-protected amino acids in solution are close to the rates of deprotection of amino-acid residues in a resin-bound peptide chain.

Lys(Z), which was deprotected 57 times faster than Thr(Bzl) in 50% TFA, is too unstable for use when the α-amino group is protected by Boc. Since the addition of electron-withdrawing substituents to Z is known to increase its stability toward acid,[8-13] the stability of six chlorinated derivatives of Lys(Z) toward 50% TFA was examined (Table II). The 4-chloro derivative, which was

Table II
Apparent First-order Loss of Chlorinated Benzyloxycarbonyl(Z) Groups from Lysine in 50% TFA--CH_2Cl_2 at 20°

Protected amino acid	k_1 (10^{-4} hr^{-1})	*Relative rate*
Lys(Z)	142	57
Lys(4-ClZ)	50	20
Thr(Bzl)*	2.5	[1.0]
Lys(2-ClZ)†	2.3	0.9
Lys(2,4-Cl_2Z)†	1.8	0.7
Lys(3,4-Cl_2Z)†	0.86	0.3
Lys(3-ClZ)	0.18	0.07
Lys(2,6-Cl_2Z)	0.14	0.06

*Inserted as a standard for comparison.
†Recommended as a suitable side chain protecting group in solid-phase synthesis.

deprotected 20 times faster than Thr(Bzl), is too acid-labile. In contrast, the 3-chloro and the 2,6-dichloro derivatives were deprotected about 15 times slower than Thr(Bzl). Since the 3-ClZ group was not completely removed on treatment with HF for 1 hr at 0°, these derivatives are probably too stable for general use in solid-phase synthesis. The 2-chloro, the 2,4-dichloro, and the 3,4-dichloro derivatives, however, were deprotected at essentially the same rate as Thr(Bzl) in 50% TFA and were completely deprotected on treatment with HF for 1 hr at 0°. Thus each of the latter derivatives exhibited a stability toward acid that is suitable for the solid-phase synthesis of large peptides when Boc is used for α-amino protection.

Finally, decalysyl-valine was prepared as before but using the 2,4-Cl_2Z group to protect the ε-amino group of lysine. Chromatography of the crude product revealed the complete absence of any peptides containing more than 10 lysine residues. This result indicates that the formation of peptides that branch at the ε-amino groups of lysine residues can be avoided and confirms the prediction that protecting groups whose acid stability is close to that of Thr(Bzl) are suitable for the solid-phase synthesis of large peptides.

CHEMISTRY AND BIOLOGY OF PEPTIDES

NEW PROTECTING GROUPS FOR AMINO ACIDS IN SOLID-PHASE PEPTIDE SYNTHESIS

Donald Yamashiro, Richard L. Noble, Choh Hao Li.
The Hormone Research Laboratory, University of California, San Francisco, California 94122

THE STABILITY OF SIDE-CHAIN protecting groups in solid-phase peptide synthesis becomes increasingly important as the length of the target sequence increases. If N^{α}-Boc protection is employed along with final removal of the side-chain protecting groups by hydrogen fluoride, four necessary conditions are required: (1) the side-chain protecting groups must survive the repeated use of de-protecting agents for removal of the Boc groups, (2) these protecting groups must be removed efficiently by hydrogen fluoride, (3) the protecting groups should not give rise to side-products at any stage of synthesis and (4) the derivatives must couple efficiently to the peptide-resin. With these considerations in mind we have undertaken a study of protecting groups for those amino acids possessing side-chain functions. Since 50% trifluoroacetic acid in dichloromethane[1] is frequently used for removal of N^{α}-Boc groups, we have tested the stabilities of various N^{α}-acetylamino acid amide derivatives toward this reagent (Table I).

It has been reported that γ-benzyl protection of glutamic acid is not entirely stable,[2] and in some preliminary tests we found that γ-benzyl glutamate lost 5% of the benzyl protection in 5.5 hours. When the test was carried out with the N^{α}-acetyl amide derivative (Table I) where the influence of the amino and α-carboxyl groups is removed, the protection was found to be more stable. It is in fact the most stable derivative listed in Table I. It was for

this reason that the tests were extended to the acetylated amides of other amino acid derivatives. The difficulty of extrapolating results of experiments performed in solution to those on solid phase is recognized, but we have proceeded on the assumption that the reactions are several times slower on solid phase than in solution. All the side-chain protecting groups shown in Table I are completely removed in hydrogen fluoride in 10 to 15 minutes at 0° and we refer to these as standard test conditions.

*Correct elemental analyses were obtained for all compounds.

†Solvents used: BAW, *n*-butanol-acetic acid-water (4:1:1); CM, chloroform-methanol (1:1).

Of the basic amino acids it is known that N^{ε}-benzyloxycarbonyl (Z) protection of lysine is not entirely stable.[3] We have prepared N^{ε} protected Lys(*p*-BrZ) (Table II) and have found it to be four times more stable to 50% trifluoroacetic acid in dichloromethane than the parent Z compound in both solution (Table III) and on solid phase.[4] Both protecting groups were about four times more stable on solid phase than in solution. More recently we have prepared[5] the *o*-bromo isomer (see Table II) and found it to be 60-fold more stable than the Z protection (Table III).

#Estimated by absorption at 295 nm in 1*N* NaOH.

Both new protecting groups are removed completely in HF under standard test conditions. It is of interest to note that these conditions were not sufficient to completely remove the *m*-BrZ protection.

For histidine and arginine we have recently employed N^{im}-Boc and N^{G}-tosyl protection, respectively, in the

synthesis of the heptapeptide[6] Ala-His-Arg-Leu-His-Gln-Leu (I) which occurs in human growth hormone[7,8] (HGH). Use of these protecting groups in the synthesis[9] of the nonadecapeptide α^{1-19}-adrenocorticotropic hormone has further demonstrated the usefulness of this combination. In the case of the heptapeptide I nitro protection of arginine led to substantial amounts of side-products containing ornithine whereas tosyl protection gave no such difficulties.

For protection of the cysteine thiol group the advantages of *p*-methoxybenzyl protection over that of benzyl protection are known.[10] The results in Table I indicate, however, that a problem of stability of the former to TFA could arise for very large peptides. In an effort to find a protecting group of intermediate stability between the *p*-methoxybenzyl and benzyl protections we prepared[11] *N*$^{\alpha}$-acetyl-*S*-(3,4-dimethylbenzyl) cysteinamide (see Table II). The derivative lost only 0.2% of its protection in TFA (Table III). Furthermore, the protecting group was completely removed in HF under standard test conditions. The suitability of this protecting group for cysteine was then demonstrated by synthesis of the C-terminal cyclic dodecapeptide[11] of HGH Val-Gln-Cys-Arg-Ser-Val-Glu-Gly-Ser-Cys-Gly-Phe.

The serious instability of benzyl protection of the tyrosine hydroxyl group suggested by the data in Table I led to an examination of the *m*-bromobenzyl and 2,6-dichlorobenzyl protecting groups (see Table II). Both were found to be about 50-fold more stable than benzyl protection (Table III), and both were removed completely in HF. We synthesized[4] the octapeptide Phe-Lys-Gln-Thr-Tyr-Ser-Lys-Phe (II) occurring in HGH with *m*-bromobenzyl protection of tyrosine in addition to *p*-BrZ protection of lysine. Peptide II was isolated in good yield and with slightly less by-product formation than in a synthesis where benzyl protection of tyrosine was employed. The by-products, as judged by amino acid analyses, are presumably octapeptide II containing an altered tyrosine residue.[13] Although a benzyl type of protection for tyrosine can be stabilized to TFA treatment and used with success, by-product formation in HF is exceedingly difficult to eliminate entirely.

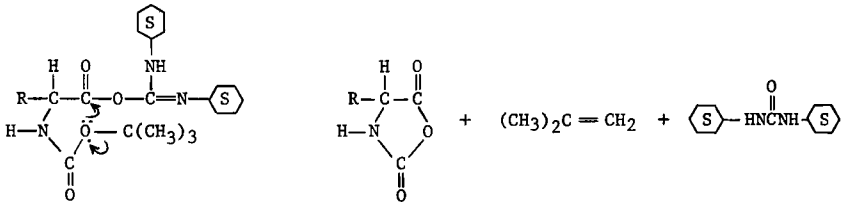
CHEMISTRY AND BIOLOGY OF PEPTIDES

EXPERIMENTS WITH ACTIVE ESTERS IN SOLID-PHASE PEPTIDE SYNTHESIS

M. Bodanszky, R. J. Bath, A. Chang, M. L. Fink, K. W. Funk, S. M. Greenwald, Y. S. Klausner. Department of Chemistry, Case Western Reserve University, Cleveland Ohio 44106

THE APPLICATION OF ACTIVE ESTERS in solid-phase peptide synthesis[1] (SPPS) was proposed earlier.[2,3] Subsequently, the use of some active esters led to successful syntheses in some cases,[4] while in other instances difficulties[5] and even failure[6] were reported. Nevertheless, there are good reasons to persist with the search for new active esters, specially designed for SPPS. The most general method of acylation through activation of acylamino acids with dicyclohexylcarbodiimide[1] (DCC) requires "global protection"[7] while the use of active esters for the same purpose[2] allows considerable freedom in this repect, *e.g.*, side chain hydroxyl and carboxyl groups can be left unprotected. This detail becomes quite important if ammonolysis[2] or alcoholysis[3,8] is planned for the removal of the completed chain. An additional problem related to activation with DCC was recognized with the surprising observation[9] that the addition of DCC to solutions of Boc-α-amino acids in dichloromethane or dimethylformamide, *etc.* results in the formation of ninhydrin positive byproducts, one of which is the free amino acid. All common Boc- and Aoc-α- amino acid derivatives were tested and all showed decomposition, while Boc-β-alanine did not. In retrospect this side reaction should not be surprising: acidolytic removal of protecting groups is based on the presence of groupings ready to form carbonium ions, while activation rests on an electron-withdrawing substituent. An interaction between

two oppositely polarized centers within the same molecule is to be expected: higher activation or higher sensitivity



to acids of the protecting group should render the lability of the protected and activated derivatives of amino acids a serious problem. At higher temperatures, benzyloxycarbonyl amino acid chlorides yield benzylchloride and *N*-carboxyanhydrides (NCA's). The decomposition of biphenylylisopropyl *p*-nitrophenyl carbonate[10] may provide a second analogy for the intramolecular displacement on *O*-Boc-aminoacylisoureas. Our investigations so far have not furnished convincing evidence of an NCA intermediate, but the decomposition itself cautions against uncritical activation with DCC in SPPS. Moderately active esters may not present similar problems and therefore their application in SPPS could be well justified.

The low rates of acylation with hindered *p*-nitrophenyl esters[11,12] prompted experiments with different active esters. Hindrance by the resin-matrix and by the growing peptide chain[13,14] can be compensated by appropriately selected active esters, as shown in Table I. The values in Table I were obtained in a solvent chosen for reasons of convenient measurements: ethyl acetate. The rate of aminolysis of *p*-nitrophenyl esters is about an order of magnitude lower in ethyl acetate than in dimethylformamide.[12] The solvent dependence of aminolysis rates is much less pronounced in the case of *o*-nitrophenyl ester (Table II). This favorable property together with their higher reactivity, reflected also in ir frequency of their carbonyl bands (Table III), were considered auspicious for further experimentation. The experiments in progress aim at the development of optimal conditions for the preparation of *o*-nitrophenyl esters of Boc-α-amino acids and for their application in SPPS.

Table I

Rates of Reaction of Different Active Esters with the Growing Peptide Chain*

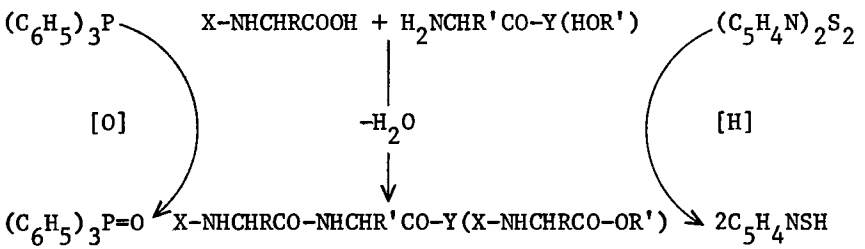
CHEMISTRY AND BIOLOGY OF PEPTIDES

PEPTIDE SYNTHESIS BY OXIDATION-REDUCTION CONDENSATION

Teruaki Mukaiyama, Masaaki Ueki, Rei Matsueda.*†
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo, Japan

IT WAS ESTABLISHED THAT various peptides and amino acid active esters are prepared without any accompanying side reactions by the oxication-reduction condensation method with use of triphenylphosphine (TPP) and 2,2'-dithiodipyridine (DTP) as shown in the following scheme.[1]



This new method is characterized by the generation of an active dehydrating agent, a phosphorane, in the reaction vessel from two components which are individually stable and safely stored. It is also a favorable feature for use in solid-phase synthesis that the two co-products produced

†Present Address: Product Development Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo, Japan.

along with peptides are very soluble in the usual organic solvents including methylene chloride. A most important merit is the attachment of the first amino acid to the resin support by the same procedures using the same reagents as for subsequent chain elongations.

All Boc-amino acids are incorporated to the hydroxymethyl resin by esterification to the extent of 0.11-0.44 mmol/g simply by shaking for 24 hr at ambient temperature with TPP-DTP in methylene chloride or *N*,*N*-dimethylformamide (DMF), Table I. Boc-dipeptides were also attached to resin under the same conditions[2] (Table I).

Table I

Attachment of BOC-Amino Acids and Peptides to Hydroxymethyl Resin by Oxidation-Reduction Condensation*

Boc-Amino Acid	*Solvent*	*Content (mmol/g)*	*Boc-Amino Acid and Boc-Peptide*	*Solvent*	*Content (mmol/g)*
Boc-Asn	DMF	0.19	Boc-Gly	CH_2Cl_2	0.44
Boc-Gln	"	0.21	Boc-Ala	"	0.25
Boc-Arg(NO_2)	"	0.12	Boc-Phe	"	0.38
Boc-Try	"	0.12	Boc-Pro	"	0.16
Boc-Cys(Bzl)	CH_2Cl_2	0.18	Boc-Ileu	"	0.11
Boc-Met	"	0.15	Boc-Ala-Ala	"	0.11
Boc-His(Bzl)	DMF	0.44	Boc-Lys(Z)-Phe	"	0.26

* 3 Equiv triphenylphosphine-2,2'-dithiopyridine + Boc-amino acid shaking with hydroxymethyl resin for 24 hr at room temperature.

A solid-phase synthesis of [Phe^2]-lysine-vasopressin by oxidation-reduction condensation was tried starting from Boc-Gly-resin obtained as described above. Couplings were performed by a 2+(3+4) fragment condensation on the tetrapeptide-resin Aoc-Cys(MeOBzl)-Pro-Lys(Z)-Gly-resin, prepared stepwise. The first fragment (Boc-Phe-Gln-Asn, 3 equiv) was introduced by shaking with 3 equiv of TPP-DTP and 6 equiv of 2(1H)-pyridinethione in DMF for 8 hr at -15° and 2 hr at ambient temperature. After cleavage of Boc by TFA-CH_2Cl_2(1:1,v/v) and neutralization, the fragment Boc-Cys(Bzl)-

Phe (3 equiv) was coupled by shaking with 3 equiv of TPP-DTP in CH_2Cl_2 for 8 hr at ambient temperature. Protected nonapeptide amide was obtained in 62% yield based on Gly by ammonolytic cleavage from protected peptide resin and purification by Sephadex LH-20 chromatography (DMF). Amino acid ratios: Cys 0.96, Phe 2.02, Glu 1, Asp 0.98, Pro 0.97, Lys 1.02, Gly 1.04, NH_3 3.31. One hundred mg of this protected nonapeptide amide showed 2840 units of pressor activity after deprotection by HF at room temp for 1.5 hr and oxidative cyclization by aeration at pH 6.7 for 3 hr.

In similar fashion, the nonapeptide amide corresponding to the sequence (2-10) of LH-RH[3] was also successfully synthesized. Fragment condensations with Boc-Ser(Bzl)-Tyr(Bzl)-Gly (1.5 equiv) and Boc-His(Tos)-Trp (3 equiv), were mediated for 24 hr with TPP-DTP in methylene chloride to give Boc-His(Tos)-Trp-Ser(Bzl)-Tyr(Bzl)-Gly-Leu-Arg(NO_2)-Pro-Gly-resin. Ammonolytic cleavage and purification by Sephadex LH-20 (elution by DMF) and Avicel (BuOH-AcOH-H_2O, 4:1:1) afforded protected nonapeptide amide monohydrate in 48% yield based on Gly. Amino acid ratios: His 1.01, Ser 0.94, Trp 0.82, Tyr 0.96, Gly 2.04, Leu 1, Arg 0.88, Pro 0.94, NH_3 1.38. All protecting groups were removed by HF in the presence of anisole and 2(1H)-pyridinethione. After neutralization with Amberlite IRA-400 in methanol, the decapeptide (LH-RH) was obtained by reaction with pyroglutamic acid pentachlorophenyl ester in DMF. The crude synthetic product obtained was converted to the acetate form. Purification was carried out by Sephadex G-25 (1 *M* acetic acid), CM-Sephadex C-25 (0.15 *M* ammonium acetate) and finally by Sephadex G-10 (1 *M* acetic acid). LH-RH was isolated as diacetate trihydrate. Amino acid ratios: Glu 1.02, His 0.98, Trp 0.84, Ser 1.01, Tyr 0.99, Gly 2.06, Leu 1, Arg 0.92, Pro 0.96, NH_3 1.35. Synthetic product showed higher activity than natural LH-RH (AVS 77-33#215-269).

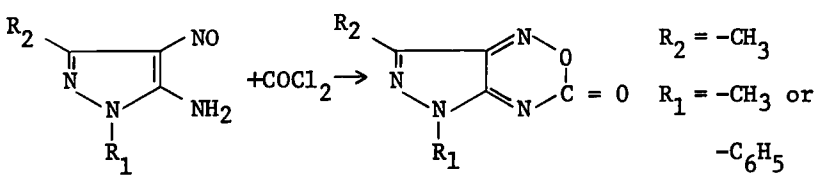
PEPTIDE SYNTHESIS THROUGH 4-NITROSO-5-AMINO-PYRAZOLE INSOLUBLE ACTIVE ESTERS

M. Guarneri, R. Ferroni, P. Giori, C. A. Benassi.
Istituto di Chimica Farmaceutica, Università di Ferrara, Ferrara, Italy

THE USE OF INSOLUBLE ACTIVE ESTERS derived from crosslinked polymers and *N*-protected amino acids in the synthesis of peptides has been previously described.[1-6] Very recently Fridkin *et al.*[7] investigated the preparation and the use of *N*-*t*-Boc-amino acid esters of a poly (ethylene-*co*-*N*-hydroxymaleimide) in order to overcome the difficulties encountered in peptide synthesis by using other polymeric reagents.

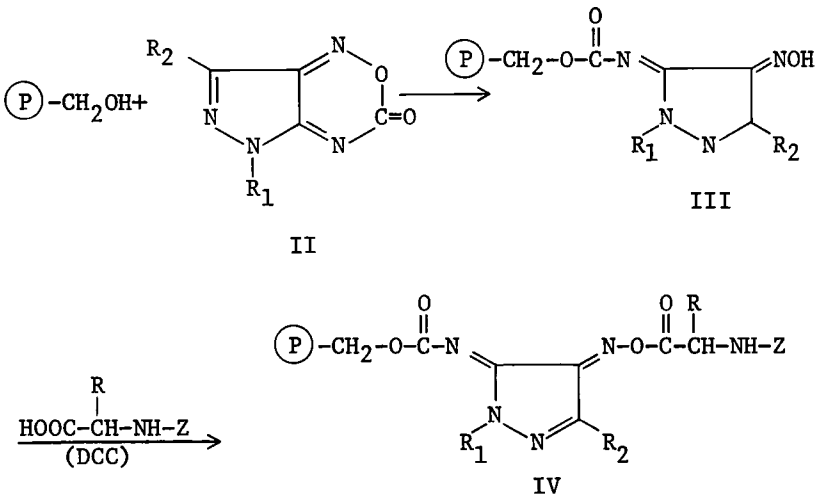
We had already reported[8] the use of 1-phenyl-3-methyl-4-nitroso-5-aminopyrazoline esters (OPmp-esters) in peptide liquid phase synthesis. We describe now the preparation of insoluble active esters derived from *N*-protected amino acids and a styrene-2% divinylbenzene polymer into which a similar pyrazole derivated is inserted. After unsuccessful attempts to introduce the pyrazole handle to a aminomethyl polymer we attained the object by reacting a hydroxymethyl styrene-2% divinylbenzene-polymer[9] with a pyrazolo-oxadiazinone II, synthetized from 4-nitroso-5-aminopyrazoles I and phosgene:



I II

Scheme I

Compound II easily reacts with the hydroxymethyl function of the polymer to give a green colored derivative III which forms active esters with Z, Boc and Nps protected amino acids when suspended in methylene chloride or dioxane in the presence of DCC as a coupling agent. The best results are obtained when $R_1=R_2=CH_3$ giving orange colored *N*-5(polystyryl-4-methyloxycarbonyl)-imino-4-oximino-1,3-dimethyl-2-pyrazoline esters (OPsp esters, IV) of *N*-protected amino acids.



Scheme II

As it appears from Table I, difficulties have been encountered to introduce sterically hindered amino acids as isoleucine for which a 48 hr reaction time has been required.

The polymeric orange colored active esters III react very rapidly with nucleophiles in a molar ratio of 1:1 at room temperature. The reaction is completed with benzylamine in few seconds and with amino acids and peptide esters between 15 and 60 min.

The synthesis of several model dipeptides as well as of the N-terminal hen egg-white lysozyme tetrapeptide Z-Lys(Z)-Val-Phe-Gly-OEt was carried out with a high yield (80% overall yield for the lysozyme tetrapeptide). Moreover, these OPsp esters present the advantage that coupling reaction can be followed from the discoloration of the polymer that reverts to green colored at the end of the reaction.

Table I

N-Protected Amino Acid Esters of *N*-5(polystyryl-4-methyloxycarbonyl)-imino-4-oximino-1, 3-dimethyl-2-pyrazoline (OPsp esters)

Amino acid derivative	*Acylation reaction time (hr)*	*nmol of amino acid bound/g of polyester*
Z-Gly-OH	4	0.85
Z-Phe-OH	3	0.99
Z-Val-OH	3	1.04
Z-Lys(Z)-OH	4	0.97
Boc-Gly-OH	5	0.90
Boc-Val-OH	24	0.54
Boc-Leu-OH	24	1.00
Boc-Ileu-OH	48	0.24
Nps-Phe-OH	5	0.58

The acylation reaction is carried out in methylene chloride using an equivalent of polymer with 1-3 equivalents of *N*-protected amino acid and dicyclohexylcarbodiimide as coupling agent.

CHEMISTRY AND BIOLOGY OF PEPTIDES

A SUITABLE REGENERABLE, SOLID-PHASE COUPLING REAGENT FOR AUTOMATED PEPTIDE SYNTHESIS*

J. Brown, D. R. Lauren, R. E. Williams. Division of Biological Sciences, National Research Council of Canada, Ottawa, Ontario, Canada K1A OR6

THE REAGENT EEDQ (*N*-ethyloxycarbonyl-2-ethyloxy-1,2-dihydroquinoline), first described by Belleau and Malek,[1] is finding increasing application in the field of peptide synthesis. When this reagent is used to synthesize a peptide ethanol, carbon dioxide and quinoline are formed as by-products. Removal of the quinoline from the reaction product can sometimes constitute a problem. However, if the reagent were to be incorporated into an insoluble polymer this problem could be overcome. Filtration of the reaction mixture would remove the insoluble quinoline polymer produced during the reaction and the protected peptide could then be isolated by simply evaporating the solvent. In addition, the quinoline polymer could be reactivated to recover the coupling reagent.

Polymerisation of 6-isopropenylquinoline, styrene and divinylbenzene (200:300:8 w/w/w/) gave us[2] the desired insoluble quinoline polymer I, Figure 1. Nitrogen analysis of the product indicated approximately 1.33 mmol nitrogen as (N_2) per gram. Activation of the polymer by reaction with ethyl chloroformate, ethanol and triethylamine in methylene chloride solution[3] afforded the solid-phase coupling reagent II, Figure 1.

The number of "active sites" per gram was assayed by reacting a known weight of resin with an excess of Dnp-Leu and Gly-OEt. Isolation of the product by thin-layer

*Issued as NRCC No. 12864.

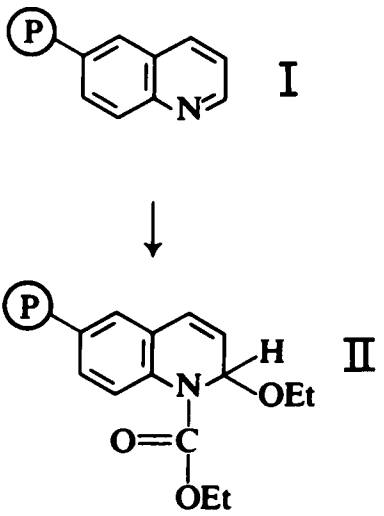

Figure 1: Solid-phase coupling reagent. I, Quinolyl polymer; II, *N*-ethyloxycarbonyl-2-ethyloxy-1,2-dihydroquinolyl polymer (EEDQ polymer); P , crosslinked polystyrene

chromatography and colorimetric estimation of the amount formed allowed calculation of the number of "active sites" per gram. Several batches of resin have been activated and assayed in this manner and found to contain between 0.2 and 0.5 mmol "active sites" per gram of resin.

The preparative utility of the insoluble reagent was assessed by coupling Z-Phe and Gly-OEt on a 0.5 mmol scale. The coupling reaction was carried out in methylene chloride solution (20 ml) using a 1.1 molar excess of the reagent. Work-up of the reaction involved only filtration and gave a crude yield of 84%. One crystallisation from ethyl acetate-petrol (30-60°) gave pure product in 71% yield.[2] Similarly, Z-Phe and Leu-OBzl were coupled (1 mmol scale) and gave a crude yield of 91%. Crystallisation from ethyl acetate-petrol (30-60°) gave pure product in 74% yield (m.p. 96-98°C; $[\alpha]_D$ -16.0 ± 0.3° (*c* 2.0, acetic acid); C,71.75; H,6.91; N,5.75. $C_{30}H_{34}N_2O_5$ requires C,71.69; H,6.82; N,5.58.). Repetition of this latter reaction using the monomeric reagent EEDQ in solution showed only a slight increase in the overall yield of pure product (86%).

Racemisation caused by each form of the "quinoline" coupling reagent was assayed under standardized reaction conditions by using the method of Izumiya *et al.*[4] This entailed preparation of the tripeptide, Gly-Ala-Leu, and separation of the diasteriomeric tripeptides by ion-exchange chromatography. Both forms of the reagent produced 6.0% of the undesired Gly-D-Ala-L-Leu.

These results, along with the previously demonstrated regenerability of the polymer,[2] suggest that this solid-phase coupling reagent could be profitably applied to the automation of peptide syntheses.

CHEMISTRY AND BIOLOGY OF PEPTIDES

SOME PROBLEMS IN SOLID-PHASE PEPTIDE SYNTHESIS

John Morrow Stewart, Gary R. Matsueda. Department of Biochemistry, University of Colorado School of Medicine, Denver, Colorado 80220

WHILE NEW TYPES OF RESIN SUPPORTS will probably eventually give significant improvements in solid-phase peptide synthesis, good results can usually be obtained with the currently used polystyrenedivinyl benzene resin supports if certain factors are taken into consideration. Especially important are crosslinking of the resin and the use of solvents and reagents which swell the resin maximally.

The encephalitogenic peptide of the myelin A protein, Thr-Thr-His-Tyr-Gly-Ser-Leu-Pro-Gln-Lys-Gly, has been reported to be impossible to synthesize by the solid-phase method, because of failure of deprotection at two places.[1] Synthesis of this peptide on a 1%-crosslinked resin, using TFA-chloroform (1:3) for deprotection, and chloroform for DCC coupling (2.5 x reagents), afforded the desired peptide in good yield, in a perfectly routine synthesis. Monitoring of coupling reactions by the ninhydrin reaction[2] showed that all went to completion within the usually allotted times. All but the first three were complete within 10 min. When the synthesis was repeated on a 2% crosslinked resin, using the same reagents, the coupling of glutamine (nitrophenyl ester) and proline were incomplete in four and two hours respectively, and uncoupled chains were blocked by acetylation with acetylimidazole. There was no evidence of significant failure of deprotection, and the desired product was still obtained, although in lower yield.

Further evidence of the importance of resin crosslinking was obtained in the synthesis of the peptide described by Folkers[3] as having luteotropin releasing activity,

<Glu-Tyr-Arg-Trp-NH_2. When the synthesis of this peptide was attempted on a 2% crosslinked chloromethylated resin, no coupling reaction was complete in 2 hr, and acetylation was used at every step. In contrast, the synthesis on a 1% resin went smoothly, with all coupling reactions being complete within 30 min. In each case, ammonolysis of the peptide-resin gave the desired tetrapeptide amide.

The peptide Pro-Pro-Thr(Bzl)-Ile-Val-Val-His(Tos)-Gly is proposed as a very difficult sequence for use as a test peptide to study effectiveness of resins, solvents and reagents. It contains the amino acids found to be most difficult to couple in solid-phase synthesis.[4] Histidine is included as a marker for detection of terminated sequences. Synthesis of this peptide on aliquots of a 1% crosslinked Gly-resin (0.36 mmol/g) was used to compare chloroform and dichloromethane as solvents for synthesis. Deprotection was by 30 min treatment with 25% TFA in the test solvent. Indole (1 mg/ml) was routinely included as a scavenger in this reagent. Although the test peptide does not contain tryptophan, any aldehydes or anhydride present in the reagent could cause undesirable termination of any peptide. A pre-wash with the reagent was used to avoid excessive dilution of the reagent by solvent in the resin. Neutralization was by 5 min treatment with 10% triethylamine in the test solvent, following a pre-wash. For coupling reactions, 2.5 equivalents of Boc-amino acid and DCC were used.

Although chloroform has been used in this laboratory recently for many syntheses, dichloromethane appears to be better for the synthesis of this peptide. When chloroform was used throughout, no coupling reaction went fully to completion in 2 hr, as shown by persistence of weak ninhydrin color on the resin. Acetylation with acetic anhydride-triethylamine or acetylimidazole was used at each step. As previously reported,[5] acetylimidazole appears to be more effective as a terminating agent. When dichloromethane was used throughout, or when deprotection was in the chloroform reagent and coupling in dichloromethane, only coupling of threonine and the first proline were incomplete in 2 hr. Examination of the crude products by paper electrophoresis showed that the desired peptide was obtained as the major product from the dichloromethane and chloroform-dichloromethane runs, while from the run using chloroform only, about half of the product consisted of acetylated peptides (ninhydrin negative, Pauly positive). The observed better result with dichloromethane was surprising, since chloroform swells the resin slightly better than dichloromethane, and has a lower dielectric constant.

Under optimum conditions of resin crosslinking and solvent, most solid-phase coupling reactions go very rapidly, and are complete within ten minutes. Monitoring of coupling can lead to significant acceleration of overall synthesis rates. When deprotection is monitored, this should be done on the amine salt of the resin, so that the peptide-resin is not left in the free amine form during the monitoring process.

With increasing importance of peptide amides, the benzhydrylamine (BHA) resin proposed by Marshall[6] has received much attention. Crosslinking is even more important in this resin, and hindered Boc-amino acids are difficult to attach to the 2% crosslinked BHA resin. These C-terminal residues are also difficult to remove from the resin by acid hydrolysis. HCl-dioxane gives very poor removal, HCl-propionic acid[7] gives better removal, but for quantitative removal it is necessary to cleave the amino acid-resin with HF.

Several general principles should be followed to minimize peptide-resin steric interactions. 1) The lowest degree of crosslinking of the resin consistent with resin stability should be used. 2) The chloromethylation should be conducted very carefully to avoid additional crosslinking.[8] The degree of chloromethylation should be kept low, and the temperature and time of the reaction should be carefully controlled. 3) The first amino acid should be esterified to the resin in a solvent (*e.g.*, ethanol) which does not swell the resin extensively, thereby limiting substitution to the most accessible sites on the resin. 4) All of the reactions of the synthesis should be done in solvents which swell the resin maximally. Pure trifluoroacetic acid does not swell the resin appreciably, and is not an effective deprotection reagent for solid-phase synthesis. The 25% trifluoroacetic acid reagent is an excellent swelling solvent and a very effective reagent.

CHEMISTRY AND BIOLOGY OF PEPTIDES

SYNTHESIS OF ENCEPHALITOGENIC PEPTIDES ON 1% CROSSLINKED POLYSTYRENE RESIN

Raymond Shapira, Frank Chuen-Heh Chou, Robert F. Kibler.
Department of Biochemistry and Medicine, Emory University, Atlanta, Georgia 30322

WE HAVE BEEN SUCCESSFUL in using the 1% crosslinked polystyrene resin beads from Bio-Rad* to synthesize the encephalitogenic decapeptide Thr-Thr-His-Tyr-Gly-Ser-Leu-Pro-Gln-Lys (I) and analogs of I. Previously described difficulties in deblocking[1] and coupling using 2% crosslinked resin were virtually eliminated by using the 1% crosslinked resin.

Chloromethylated polystyrene-1% divinylbenzene resin was esterified with the first Boc-amino acid. Double deblocking at 0°C in 5.6 *N* dry HCl in dioxane and double coupling (using DCCI) at room temperature usually gave excellent yields as determined by the ninhydrin test[2] and by amino acid analysis. Cleavage of the peptides from the resin with liquid hydrogen fluoride in purified anisole under a stream of dry nitrogen was essentially quantitative. The resulting peptides showed a high degree of purity based on chromatography, using a 16 feet Sephadex G-25 column, and on amino acid analysis. The following modifications have been successfully made:

1. Replacement of Lys with Arg.
2. Elongation of the C-terminal with Gly, and Ala-Gln-Gly.
3. Elongation of the N-terminal with Arg and Ala-Arg.
4. Substitution of Bzl-His and Dnp-His for His.
5. Substitution of other aromatic residues for Tyr.
6. Combinations of these modifications

*Bio·Rad Laboratories, Richmond, Ca 94804.

The synthetic peptides are being tested for encephalitogenic activity in rabbit, rat, guinea pig, and monkey. The nature of the encephalitogenic peptide receptor site in these species will be studied and the ability of these peptides to produce and block the disease. We have reported previously[3] that decapeptide I possesses moderate encephalytogenic activity. This peptide occupies an active site (positions 66-75) of bovine basic myelin protein (170 residues) which produces experimental allergic encephalomyelitis in animals, characterized clinically by onset of weakness, ataxia, and other neurological signs 2 to 3 weeks after challenge and pathologically by multiple perivenular areas of demyelination and cellular infiltration.[4]

CHEMISTRY AND BIOLOGY OF PEPTIDES

DIFFICULTIES IN SOLID-PHASE PEPTIDE SYNTHESIS OF SOME ANALOGS OF ANGIOTENSIN II

M. C. Khosla, R. R. Smeby, F. M. Bumpus. Research Division, Cleveland Clinic Foundation, Cleveland, Ohio 44106

DURING SYNTHESES OF ANGIOTENSIN II analogs by the solid-phase procedure of Merrifield some problems were observed. Our experience with these problems and the efforts made to overcome these difficulties are reported here.

Formation of Failure Sequence Due to Intramolecular Aminolysis

Solid-phase synthesis of the octapeptide, Asp-Arg-Val-Tyr-Ile-His-Pro-MePhe ([8-*N*-methylphenylalanine]-angiotensin II) did not yield the desired peptide. Repetition of this synthesis and analysis at each step revealed that almost 85% of Pro-MePhe was cleaved from the polymer during neutralization of HCl.H-Pro-MePhe-polymer with 10% Et_3N in DMF. Filtrates yielded *cyclo*(-Pro-MePhe-) while further coupling resulted in direct esterification of Boc-His(Bzl)-OH on the hydroxymethyl polymer so formed. The compound formed in the original synthesis was therefore identified as the N-terminal hexapeptide of angiotensin II. Cleavage of Ala-MePhe (80%), Pro-Pro (60%) and Ala-Pro (40%) also occurred from respective dipeptide polymers. Gisin and Merrifield[1] observed similar cleavage with H-D-Val-Pro-polymer and reported that the cleavage of dipeptide was catalyzed by carboxylic acid and took place during the next coupling step. These conclusions are surprising since the formation of diketopiperazine is supposedly due to the stabilization of the *cis* conformation which is possible in

peptide units containing proline[2] (or other secondary amino acids); and ring closure is further expected to be accelerated if the α-amino group is not protonated. However, our conditions of neutralization step are different than those reported by Gisin and Merrifield[1] in that these authors used 5% N, N-diisopropylethylamine in CH_2Cl_2 for neutralization of the HCl-salt.

The failure sequence was avoided by not neutralizing the HCl-salt and carrying out condensation with Boc-His (Bzl)-OH either through *N*-ethyl-*N'*-(3-dimethylaminopropyl) carbodiimide hydrochloride salt (EDAC) in $CHCl_3$ at -10 to 0° or through the corresponding pentachlorophenyl ester in DMF. However, racemization of histidine residue was higher with pentachlorophenyl ester than with EDAC.

Racemization of Histidine Residue During the Coupling Step

Earlier studies in our laboratories and by Windridge and Jorgensen[3] indicated that almost 35-40% racemization of histidine residue occurred during solid-phase synthesis of angiotensin II analogs. We have now been able to isolate[4] the D-histidine containing octapeptides from the L-histidine analogs of angiotensin II by ion-exchange chromatography with buffers of varying pH followed by partition chromatography on Sephadex G-25. Steric homogeneity of these octapeptides was determined by incubating the acid hydrolysates with L-amino acid oxidase (*Agkistrodon p. piscivorus*). Pressor as well as antagonistic properties of the D-histidine containing analogs of angiotensin II were found to be very low as compared to the L-histidine analogs. For example, [Ile^5,D-His^6]-angiotensin II possessed 4% of the pressor response of the parent hormone, Hypertensin Ciba.

Studies to avoid racemization revealed that extensive racemization of the histidine residue occurred (30-40%) when DMF was used as a solvent for coupling Boc-His(Bzl)-OPcp or Boc-His(Bzl)-OH with H-Pro-Leu-polymer through DCC or EDAC. Coupling of Boc-His(Bzl)-OH by "reversed" DCC procedure in CH_2Cl_2 gave similar results. Racemization was suppressed (15-20%) when Boc-His(Bzl)-OH was condensed in CH_2Cl_2 or $CHCl_3$ at -10° or when the imidazole moiety in histidine was protected with the tosyl group. Use of *N*-hydroxysuccinimide in CH_2Cl_2 along with DCC reduced the racemization considerably but did not abolish it as reported;[3] besides, the coupling reaction was very slow and the yields of the desired peptides were lowered due to the formation of β-alanyl peptides as a side product.[5] Azide coupling[6]

with Z-Ile-His(Bzl)-N_3 did not give racemization but the condensation reaction could not be completed even after shaking for 3 days at 5°.

Formation of Side Products During Cleavage of Peptides with HBr

During the synthesis of Tyr-Ile-His-Pro-Leu, peptides were removed at every intermediate stage with HBr to (a) judge the progress of synthesis and to (b) obtain intermediate peptides. In spite of the correct amino acid ratios in the peptide polymer as well as in each cleaved peptide, tlc of the tripeptide and the tetrapeptide revealed the presence of a number of products (Figure 1). However, the

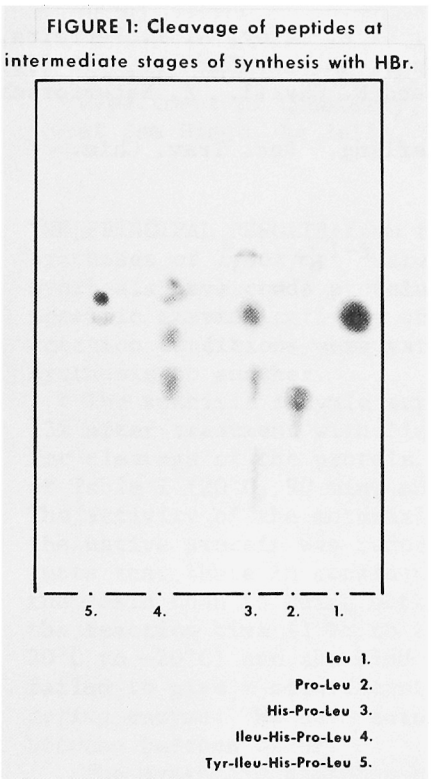

Figure 1: Cleavage of peptides at intermediate stages of synthesis with HBr.

pentapeptide showed a single homogeneous product and cleavage by transesterification of the intermediate peptides gave single components. This indicates that the formation of side products is due to cleavage with HBr and is presumably due to the peculiarity of this susceptible sequence.

CHEMISTRY AND BIOLOGY OF PEPTIDES

SOLID PHASE SYNTHESIS OF PROTEIN WITH HIGH SPECIFIC LYSOZYME ACTIVITY

Leon E. Barstow, Dennis A. Cornelius, Victor J. Hruby, Tadahisa Shimoda, and John A. Rupley. Department of Chemistry, The University of Arizona, Tucson, Arizona 85721

John J. Sharp, Arthur B. Robinson, and Martin D. Kamen. Department of Chemistry, The University of California at San Diego, La Jolla, California 92038

THE PRINCIPAL RESULTS from four solid phase (Merrifield) syntheses of lysozyme[1-3] are summarized in Table I. Each synthesis gave crude protein which had 0.5% to 1.3% the specific enzymic activity of the native enzyme even though reaction conditions were varied substantially from one synthesis to another.

The specific enzymic activity of native lysozyme is 13% after treatment with liquid HF under the condition used for cleavage of the protein resin ester in the experiments of Table I (20°C, 90 min, added Trp, Met, Gln and anisole). The activity of the material decreased further to 6% when the native protein was reduced and reoxidized. This suggests that there is considerably more active protein on the resin than is being obtained. Thus far, changes in the reaction time (1 hr to 24 hr), the temperature (from 20°C to -20°C) and the kind and quantity of additives have failed to give a significant improvement in the yield of active enzyme. We have noted great variation in quality between batches of HF.

The synthetic proteins have been characterized by several measures of enzymic activity (cell lysis, hexa-*N*-acetylglucosamine hydrolysis and glycosyl transfer) and by chromatography, UV spectra, and amino acid analysis.

Table I

Solid-Phase Syntheses Conditions and Yields

Synthesis	*1**	*2**	*3*†	*4*†
Yield of resin ester/gram of starting resin	1.8 g	3.7 g	2.2 g	2.4 g
Yield of crude protein/gram resin ester	60 mg	160 mg	195 mg	220 mg
Specific enzymic activity of crude protein	1.3%	0.8%	0.5%	0.8%
Equivalent of lysozyme/gram of resin ester	0.8 mg	1.3 mg	1.0 mg	1.8 mg
Leu Substitution	0.41 mm/g	0.40 mm/g	0.30 mm/g	0.36 mm/g
Deprotection Reagent	50% TFA-CH_2Cl_2 mercaptoethanol	4*N* HCl-Dioxane ethanedithiol	50% TFA-CH_2Cl_2 ethanedithiol	40% TFA-CH_2Cl_2 ethanedithiol
Deprotection Time	30 min	30 min	35 → 17 min	2 x 6 min
DCC Coupling Times	4 hr	1 to 2 hr	90 min, 60 min	15 min
Solvent	CH_2Cl_2	CH_2Cl_2,DMF,DMF urea	CH_2Cl_2,DMF	CH_2Cl_2
Number of Couplings	1	2 to 6	2	2
Nitrophenyl Ester Coupling Times	4 hr	12 to 24 hr	10 to 12 hr	6 hr DIEA 2 hr
Total Synthesis Time	8 weeks	24 weeks	7 weeks	3.5 weeks

*Synthesis carried out at Dept. of Chemistry, University of California at San Diego; ref. 3.
†Synthesis carried out at Dept. of Chemistry, University of Arizona.

At this time, substantial work has been carried out on small portions from the fourth synthesis. About 10% of the protein has the same elution volume as the native on Sephadex G-75. All of the active protein is in this fraction. A combination of Bio-Rex 70 and affinity chromatography gave protein with more than 70% the specific lytic activity of the native enzyme.

Brown[4] has found that Residue 103 is Asn instead of Asp as had been reported.[5,6] The first two syntheses of lysozyme were prepared with the published sequence. This substitution apparently does not significantly lower the enzymic activity.

Substitutions in the active site of Trp for Tyr at position 53 and Tyr for Thr at position 51 give protein material which is totally inactive. This experiment demonstrates that only molecules with a tertiary structure like that of lysozyme have the lysozyme enzymic activity.

We are continuing to work on improvements in the synthesis of native lysozyme as well as the synthesis and characterization of other lysozyme analogs.

CHEMISTRY AND BIOLOGY OF PEPTIDES

AN IMPROVED SOLID PHASE SYNTHESIS OF LH-RH/FSH-RH: A PROGRESS REPORT

Maurice Manning, Esther Coy. Medical College of Ohio, Department of Biochemistry, Toledo, Ohio 43614.

Andrew Schally. Endocrine and Polypeptide Laboratories, Veterans Administration Hospital, Department of Medicine, Tulane University, School of Medicine, New Orleans, Louisiana.

SCHALLY AND CO-WORKERS RECENTLY reported[1] the isolation from porcine hypothalami of the peptide hormone which controls the secretion of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the pituitary gland. The amino acid sequence of this hypothalamic hormone, designated LH-releasing hormone/FSH-releasing hormone, I (LH-RH/FSH-RH), was shown[2] to be:

I: <Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2
1 2 3 4 5 6 7 8 9 10

Subsequently, seven separate reports on the chemical synthesis of this decapeptide amide have thus far appeared in the literature.[3-9] In chronological order of submittal for publication, these are originating from the groups of (a) Arimura *et al.*,[3] (b) Monahan *et al.*,[4] (c) Sievertsson *et al.*,[5] (d) Geiger *et al.*,[6] (e) Matsuo *et al.*,[7] (f) Rivaille *et al.*,[8] (g) Sievertsson *et al.*[9] Reports (a-d) give no weight or percentage yield of I. Synthesis (e) resulted in an overall yield of 8% of I. Synthesis (f) afforded 10 mg of I but the overall yield appears to be low: from the data given it is not possible to calculate it but the final purification step alone resulted in only a 25% yield. Two different synthetic approaches are presented in (g) but

neither weights or percentage yields of the final purified I are given.

It is thus clear that all of these synthetic approaches possess serious shortcomings with regard to either a) synthetic strategy or b) complicated purification procedures; resulting in both instances in most unsatisfactory yields of I.

The present report deals with yet another approach towards achieving a satisfactory synthesis of LH-RH/FSH-RH and to thereby provide a readily reproducible method for the synthesis of analogs of this hormone.

The approach followed is, with minor modifications, essentially that used for the solid phase synthesis of oxytocin[10] as utilized for the synthesis of [4-threonine]-oxytocin.[11]

In a preliminary experiment, the protected decapeptide resin: <Glu-His(Bzl)-Trp-Ser(Bzl)-Tyr(Bzl)-Gly-Leu-Arg(Tos)-Pro-Gly-Resin (II) was synthesized by the Merrifield Method.[12] Starting with 3.0 g Boc-Gly-Resin (purchased from Schwartz/Mann Inc. and containing 1.2 mmole glycine) the appropriate Boc-amino acids were added in stepwise fashion following the general procedure outlined before.[11] Mercaptoethanol (1%) was utilized in the deprotection and acid washing steps subsequent to the incorporation of the trypthophan residue.[13] All coupling reactions were mediated by dicyclohexylcarbodiimide with methylene chloride being used as the coupling solvent for all residues except those involving Boc-Arg(Tos), Boc-Trp, Boc-His(Bzl) and pyroglutamic acid; for which redistilled dimethylformamide was employed. The chloride values (estimated by Volhard titration) following the neutralization presented a very curious and anomalous pattern: starting with Gly and ending with the value for ion-exchange bound chloride following the incorporation of the pyroglutamic acid residue, these values were (in mmole) i 1.56; ii 1.53; iii 1.91; iv 1.80; v 1.90; vi 1.65; vii 1.65; viii 1.65; ix 2.87; x 1.95. Thus the chloride value exhibited a big increase following the neutralization of the Arg(Tos) (iii) with the final ion-exchange bound value (x) being higher than the starting value for Gly (i). We have no explanation for these results. The protected decapeptide resin (II) weighed 4.58 g. The weight gain represents a 93% incorporation on the resin. II was ammonolyzed as described previously,[10,11] except that the reaction time was extended to three days. The cleaved resin was extracted with warm (50°) ethanol and the extract evaporated to dryness to give 1.4 g of crude product. This was recrystallized twice from methanol-ether to give the

protected decapeptide: <Glu-His(Bzl)-Trp-Ser(Bzl)-Tyr(Bzl)-Gly-Leu-Arg(Tos)-Pro-Gly-NH_2 (III) as an off-white amorphous powder (1.0 g). This represents a yield of 60% based on the glycine content of the starting resin.

III gave a satisfactory amino acid analysis and showed only one spot (R_f 0.45) with iodine and with the chlorine reagent when an aliquot was examined by tlc in the system butanol-acetic acid-water (4:1:5). M.P. 155-159° (softens to a brown globule; melts finally >200°). The poor melting point is not satisfactory and indicates the presence of an impurity. C.H.N. values have thus not yet been obtained. However, this material upon deprotection and subsequent purification gave the desired pure I in excellent yield. An aliquot (100 mg) of III was deblocked by the sodium liquid ammonia procedure.[11,14] The final medium blue color was discharged after only 10 sec. by the addition of a few drops of dry acetic acid. Upon evapoaration of the ammonia, the crude deblocked product was purified on Sephadex G-15 by a slight modification of the two step procedure used for the purification of oxytocin and analogs.[11,15] In the first step, the sample was applied to a column (2.7 x 110 cm) in 50% HOAc (1.5 ml) and washed-in with another 1.5 ml of 50% HOAc. The column was eluted with 50% acetic acid at a flow rate of 6.8 ml/hr and the elute monitored by uv absorption at 280 nm. Ninety-five fractions were collected with 4.1 ml in each of the tubes 1-52 and 2.0 ml in each of the remaining tubes. The uv absorption spectrum indicated the presence of a single large peak of peptide material in tubes 56-86 with very minor amounts of absorbing material in the tubes immediately preceding and following the peak. Thin layer chromatographic examination on precoated silica gel G plates of the material in tubes 56-86 in the system butanol-acetic acid-water (4:1:5) showed the presence of only one component, which was both Pauly positive and chlorine reagent positive, in tubes 67-78 (FI). This material gave the same R_f (0.22) as standard LH-RH/FSH-RH. Tubes 79-83 (FII) were found to contain a faint trace of a faster moving Pauly positive component (R_f 0.26) in addition to I. Upon lyophilization, FI yielded 44.1 mg and FII gave 20.0 mg of white fluffy powders. Both of these fractions were then purified separately by the second step[15] which employs a different size column (1.5 x 110 cm) and 0.2 *N* acetic acid as eluting solvent. Both FI and FII were each eluted independently at a flow rate of 12 ml/hr at a fraction size of 1.6 ml. Each gave a symmetrical peak of 280 nm absorbing material. Tlc monitoring of the FII elute indicated that the two substances present in FII had been largely

resolved. Upon lyophilization, FI and FII gave 34.0 mg and 11.0 mg respectively of I for a total of 45 mg, $[\alpha]_D^{26}$ -48.0° (*c* 1, 1% acetic acid). This represents a yield of 60% from the deblocking step and an overall yield of 30%.

The side-product from the 0.2 *M* HOAc Sephadex G-15 purification of FII gave 3.0 mg. Amino acid analysis of this material indicated that it possessed the sequence of the N-terminal heptapeptide amide of I *i.e.* it lacked one residue each of Arg, Pro and Gly.

The synthetic product, I, was shown to be chemically and biologically indistinguishable from the natural hormone. This indicates that no appreciable racemisation had taken place during the incorporation of the Boc-His(Bzl) residue, or if it had, that the D-diastereoisomer was removed during the purification of the protected decapeptide. Bioassays of synthetic I were carried out as described previously.[16] *In vivo* LH-releasing activity of I was 120% (57-305%) of the potency of purified natural LH-RH.

Conclusion

The approach outlined here must still be regarded as work in progress rather than as a desired completed project. There are obviously some strange things happening especially in regard to the synthesis on the resin. Nevertheless our results to date are encouraging and, even at this stage, the final yield of I is, to our knowledge, the most satisfactory so far reported. A fuller report will be presented elsewhere upon completion of a truly satisfactory improved synthesis of FSH-RH/LH-RH.

CHEMISTRY AND BIOLOGY OF PEPTIDES

SOLID-PHASE SYNTHESIS OF THE PENTADECAPEPTIDES VALINE-GRAMICIDIN B AND C

Kosaku Noda, Erhard Gross. Section on Molecular Structure, Laboratory of Biomedical Sciences, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland 20014

THE AMINO ACID SEQUENCE (Figure 1) of the pentadecapeptide antibiotics valine-gramicidin B and valine-gramicidin C were determined in 1964.[1] Syntheses by conventional techniques of valine-gramicidin A and isoleucine-gramicidin A (Figure 1) were reported in 1965.[2]

Figure 1: The amino acid sequences of the valine-gramicidins and of isoleucine-gramicidin A.

Recently, we completed the synthesis of valine-gramicidin A by the solid-Phase method.[3] We have now synthesized valine-gramicidin B and valine gramicidin C by the solid-phase method.

It was the objective of our studies to provide a rapid and simplified synthetic route for the antibiotics and their analogs. Moreover, the nature of the amino acid residues constituting the peptides are of interest from the point of view of solid-phase synthesis. The peptides contain: (i) three tryptophan residues, which, as is well known, undergo frequently undesirable side reactions under acidic conditions,[4] (ii) the -Val-Val-Val- sequence, which is also considered a possible source of difficulty, since it has been reported that yields of coupling are usually poor when this sterically hindered amino acid is involved,[5] and (iii) an *N*-formyl group and the ethanolamide moiety at the COOH-terminus.

Figure 2 shows the outline for the syntheses of the desired peptides. The solid-phase synthesis followed

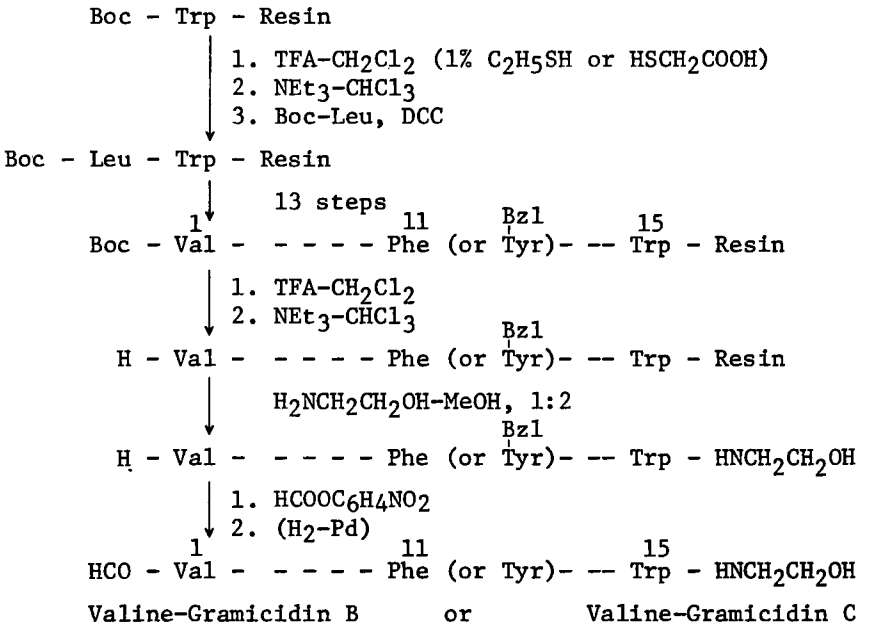

Figure 2: Outline of the solid-phase synthesis of the valine-gramicidins B and C.

essentially the general procedure of Merrifield.[6] Boc-Amino acids were used throughout, the coupling step being carried out in methylene chloride with dicyclohexylcarbodiimide. The *N*-protecting group was removed by treatment with 25% trifluoroacetic acid in methylene chloride containing 1% ethanethiol (synthesis of gramicidin B) or with 50% trifluoroacetic acid containing 1% of thioglycolic acid (synthesis of gramicidin C). In the case of the gramicidin B synthesis, the progress of amino acid coupling at each cycle was determined by the ninhydrin method of Kaiser *et al.*[7] It is noteworthy that all peptide bond forming reactions were completed within 1 to 2 hours (*cf.* Table I) even in the case of coupling of valine in the -Val-Val-Val- sequence. Throughout the gramicidin C synthesis the coupling time was fixed at four hours.

After removal of the Boc-group from the H_2N-terminal valine, the *N*-formylated pentadecapeptide ethanolamide was obtained by cleavage from the resin with ethanolamine in methanol (1:2) and subsequent *N*-formylation with *p*-nitrophenylformate. Gramicidin C was obtained by removal of the *O*-benzyl group from tyrosine by catalytic hydrogenation of the formylated pentadecapeptide ethanolamide.

The crude peptides so obtained were then purified by countercurrent distribution in a solvent system consisting of chloroform:benzene:methanol:water (1:1:1.5:0.5 by volume). Figures 3-a and 4-a show the distribution patterns of crude synthetic valine-gramicidin B and C, respectively, for 200 transfers. Each main fraction corresponding to the natural product was subjected to further distribution (Figures 3-b and 4-b). The main fractions were isolated and lyophilized from glacial acetic acid. Yields of purified material were 5% for gramicidin B and 6% for gramicidin C calculated on the basis of Boc-Trp-resin.

The products of final purification, alone or in an equimolar mixture with the natural compounds, showed single symmetrical peaks on redistribution (Figures 3-c and d and 4-c and d). The synthetic peptides showed single spots of the same R_f-value as the natural compounds on silica gel plates in thin layer chromatography in several solvent systems. Amino acid analyses are in good agreement with the amino acid compositions of the natural products (Table II).

The infrared spectra (KBr) are superimposable with those of the natural compounds (Figure 5 and 6).

The synthetic products were tested for their antibiotic activities. Against several microorganisms they were found

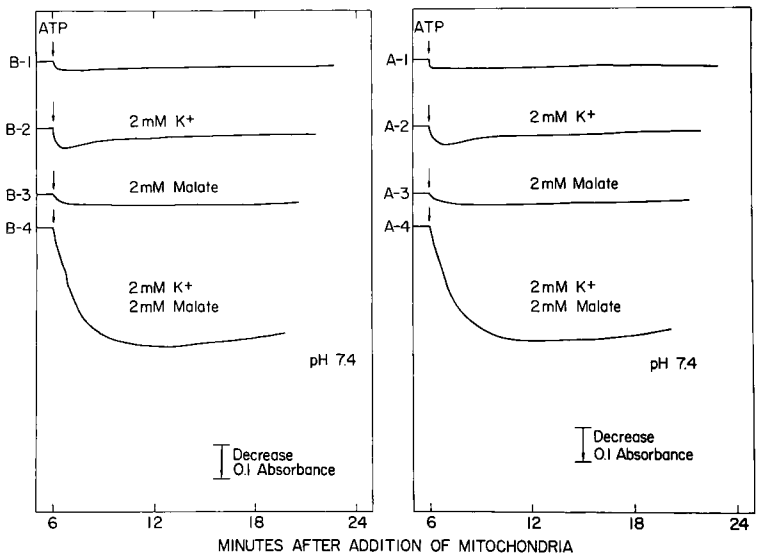

Figure 8: Valine-gramicidin C induced swelling of mitochondria; left: synthetic peptide; right: natural product

to possess the full complement of activity of the corresponding natural gramicidins (Table III). Finally, synthetic valine-gramicidin B as well as valine-gramicidin C displayed the same potential in causing mitochondrial swelling[8] as do the natural compounds, Figure 7 and 8.

We have demonstrated that the solid-phase technique, in combination with countercurrent distribution, makes readily available synthetic peptides of a high degree of purity of the gramicidin A, B, and C series. Access by synthesis to these peptides of unique physical, chemical, and biological properties occurred at a most opportune time, now that D. W. Urry and his associates[9] have demonstrated the singular type of helix which these peptides are capable of forming and that the head-to-head dimer of these gramicidins spans lipid bilayers and acts as transmembrane channel affecting ion transport.

It shall be most interesting to provide analogs of the gramicidins A, B, and C and to study their effect on ion transport across biomembranes and the ensuing biological consequences.

Acknowledgment

We gratefully record the use of a Peptide Synthesizer at Beckman Instruments, Inc. of Palo Alto, California, and the collaboration of Mr. Jon F. Harbaugh throughout the synthesis of gramicidin B. Dr. Marvin J. Weinstein and his associates of the Schering Corporation of Bloomfield, New Jersey, performed the antibiotic tests. Dr. Herbert I. Hadler determined the effect of the gramicidins on mitochondria. The IR-spectra were taken by Mr. Noel F. Wittaker.

GLOBIN DECAPEPTIDE SYNTHESIS AND LABELING FOR PARENTERAL USE

Julie Brown, Henry Brown. Sears Surgical Laboratory, Harvard Surgical Service, Boston City Hospital; Department of Surgery, Harvard Medical School.

Arnold Trzeciak. Children's Cancer Research Foundation, Boston, Massachusetts 02115.

THE INTRIGUING POSSIBILITY THAT amino acids in peptide linkage may be used in forming new hemoglobin was investigated. Previous animal experiments were done measuring effects of amino acids in peptide linkage from a peptic globin hydrolysate on hemoglobin regeneration.[1] Hemoglobin regeneration was better with amino acids in peptide linkage than with equivalent amounts of free amino acids. Using globin containing ^{14}C labeled amino acids, a decapeptide with higher specific activity than others was isolated from the peptic hydrolysate.[2] The amino acid sequence was found to be: Ser-Glu-Asp-Leu-Gly-Ala-Ser-Val-Ser-Leu.[3] It is probably from the α-chain, analogous to positions 129-138 in human hemoglobin.[4]

A peptic hydrolysate of rat globin containing ^{14}C labeled amino acids was administered intraperitoneally to rats made anemic by bleeding. This peptide, isolated from newly formed hemoglobin, again had higher specific activity than 26 other acidic peptides studied. The findings suggested incorporation of at least some amino acids from this sequence while remaining in peptide linkage.[2]

To test this hypothesis the decapeptide was synthesized. The Merrifield solid-phase method[5] was used with modifications as described by Manning *et al.*[6] in which all major steps of deprotection, neutralization and coupling are repeated. Two

percent cross-linked polystyrene was used to prepare the starting Boc-leucine resin. Dicyclohexylcarbodiimide mediated couplings using 3 equivalents of Boc-amino acids were tested for completeness by the Kaiser ninhydrin procedure.[7] Benzyl group side-chain protection was employed for Boc-Ser(Bzl), Boc-Asp(OBzl) and Boc-Glu(OBzl). N^{α}-*t*-Butyloxycarbonyl protecting groups were cleaved by successive treatments with 30 percent trifluoroacetic acid in methylene chloride and 1*N* HCl in acetic acid. Cleavage was tested for completeness by Volhard chloride titration.

The final decapeptide was cleaved from the resin by anhydrous liquid HF. The peptide was purified by repeated Sephadex G-15 gel filtrations in 0.1*N* and 0.2*N* acetic acid, respectively. The synthetic peptide had the same N-terminal serine as measured by the Dansyl and DNP techniques and amino acid analysis as the natural peptide. The synthetic and natural peptides had the same R_f value on filter paper chromatography in *n*-butanol-water-acetic acid (4:1:5). They also had the same electrophoretic mobility on filter paper at 1700 volts D.C. both in 0.2*N* acetic acid, pH 2.7 and in formic acid-dioxan-water, pH 2.1. The yield of peptide was 80% of theoretic.

A second synthesis was done using Boc-(1-^{14}C)-L-leucine. This radioactive amino acid was incorporated into amino acid position 4 but not at the C-terminal leucine. Specific activity of the peptide was 0.21 μCi/mg.

For hemoglobin regeneration experiments 50.1 mg of [1-^{14}C]-L-leucine labeled globin (10 μCi) was dissolved in 5 ml of lactated Ringer's solution. pH was brought to 7.4 with dilute sodium hydroxide. A 420 gram male rat was bled by cardiac puncture 2 ml per day for 4 days. The dissolved globin peptide was then injected intraperitoneally in divided doses 15 minutes apart. Twenty-three hours later the animal was exsanguinated by cardiac puncture. Hemoglobin was prepared from red cells and globin was separated from heme by acid acetone by previously described methods.[1,2] Specific activity of this globin was $1.3 \cdot 10^{-4}$ μCi/mg. Studies are in progress to determine specific activities of the two leucine residues in positions 4 and 10 of the isolated decapeptide.

CHEMISTRY AND BIOLOGY OF PEPTIDES

STUDIES WITH SEMISYNTHETIC NONCOVALENT PROTEIN COMPLEXES

Irwin M. Chaiken. Laboratory of Chemical Biology, National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Bethesda, Maryland 20014

CURRENT ADVANCES IN CHEMICAL SYNTHESIS of large peptides[1,2] have provided the potential for studying protein conformation and biological activity, at the level of amino acid function, by the preparation of synthetic analogues. To be sure, preparation of chemical mutants for proteins of at least several thousand molecular weight is limited by, among other things, the insolubility of large intermediates for synthesis in solution and the difficulty of obtaining pure products by solid-phase methods. Nonetheless, for the biologically active noncovalent complexes staphylococcal nuclease-T'[3] and bovine pancreatic ribonuclease-S',[4] a wide variety of structural analogues have been synthesized,[5-11] in each instance for a relatively small protein fragment which binds to a complementary native fragment. In such cases, the synthetic problem is simplified while at the same time allowing protein systems of considerable size and complexity to be examined. For both nuclease-T' and ribonuclease-S', it has now become possible to adapt solid-phase synthesis for the preparation of semisynthetic complexes of purity sufficient to allow detailed conformational and functional characterization.

One of the systems studied, nuclease-T', is the enzymically active complex obtained from intact nuclease (foggi strain) by limited trypsin treatment and composed of the two noncovalently bound fragments containing, respectively, residues 6 through 48 [nuclease-T-(6-48)] and 49 through 149 [nuclease-T-(49-149)].[3] The fragment corresponding to residues 6 through 47 has been synthesized by the Merrifield solid-phase

procedure[12,13] as described previously.[14] As reported, the resulting crude synthetic-(6-47) peptide (obtained after cleavage from resin and deblocking) is only partially effective (due to impurities) in replacing nuclease-T-(6-48) in forming an active complex with nuclease-T-(49-149). However, methods have since been developed[15,16] to obtain a highly active complex, containing synthetic-(6-47) and nuclease-T-(49-149), by a procedure involving trypsin treatment of a mixture of the synthetic and native fragments followed by phosphocellulose chromatography. The resulting semisynthetic nuclease-T' is quite similar to native nuclease-T' in the enzymic properties of specific activity and binding of substrates and inhibitors (Table I), as well as in the structural properties of fluorescence emission and stability to temperature and trypsin treatment.[16]

The ability to obtain purified semisynthetic nuclease-T' provides the basis for the preparation and detailed characterization of important semisynthetic analogues. In one case, the analogue [Asp^{43}]-semisynthetic nuclease-T', with aspartic acid replacing glutamic acid at position 43, was obtained.[17] This material was shown to be enzymically inactive. On the other hand, the analogue complex is conformationally similar to normal nuclease-T' and still able to bind both deoxythymidine-3',5'-diphosphate, an inhibitor of nuclease and nuclease-T', and calcium, an atom directly required for nuclease-T' activity and also important for conformational stabilization. Taken together with the fact that Glu^{43} is in the active site region in the crystal structure of nuclease[18] and probably nuclease-T' also,[19] the results indicate that Glu^{43} is critical for the organization of the active site of nuclease-T', either directly in hydrolysis or perhaps in the orientation of a directly participating group (such as the essential calcium ion).

By procedures similar to those used above, semisynthetic ribonuclease-S', the complex of synthetic-(1-15)(the solid-phase synthesized fragment corresponding to residues 1 through 15 of ribonuclease A[20,21] and ribonuclease-S-(21-124)(the native fragment containing residues 21 through 124 of ribonuclease), has been prepared[22,23] in a form, after sulfoethyl-Sephadex fractionation, about equally as active as native ribonuclease-S' (Table II). For this semisynthetic complex, analogues have been prepared which are labeled with either enriched carbon-13 or fluorine-19 at specific residues in the 1-15 region (Table II). Using the appropriate analogue, ^{13}C and ^{19}F nuclear magnetic resonance spectra have been obtained, in both cases allowing specific resolved resonances to be characterized and assigned to individual

atoms.[23] By such procedures, it is hoped that conformational and enzymic features of ribonuclease-S' can be defined, especially in relation to the participation of specific amino acid residues.

The semisynthetic noncovalent protein complexes described, when obtained in sufficient amounts, should be appropriate for characterization to a degree expected for native proteins and protein derivatives. Inasmuch as X-ray crystallographic studies have been, or are being, carried out for ribonuclease-S'[26] and nuclease-T',[19] it is expected that specific important semisynthetic analogues for these two complexes can be examined crystallographically, analogous to recent experiments with native abnormal hemoglobin variants.[27]

Ultimately, it is hoped that such characterizations of semisynthetic analogues will lead to an increased understanding both of detailed structure-function relationships for the specific proteins studied as well as of rules for the function of amino acids in proteins in general.

SYMPOSIUM DISCUSSIONS

Summarized by Johannes Meienhofer

THE MAJORITY OF PAPERS in this session on solid-phase peptide synthesis dealt with new methodological developments. In the discussions, however, several comments pertained to the standard procedure. Attention was drawn to the observation of small amounts of ninhydrin-positive side products when dicyclohexylcarbodiimide is added to solutions of *t*-butyloxycarbonylamino acids. Among these side products the free amino acid, dipeptide and polymerized compounds have been identified. No decomposition of this kind was observed when DCC was added to benzyloxycarbonylamino acids or with active esters of Boc-amino acids, but caution was expressed that 2-(*p*-biphenylyl)isopropyloxycarbonylamino acids (Bpoc-amino acids) might also be effected by DCC.

Several remarks were made about losses of dipeptides from peptide resins through the formation of diketopiperazines either during the neutralization step or the following (longer lasting) coupling stage (see also pp 227 to 230 This troublesome side reaction can occur whenever the second amino acid residue from the *N*-terminal (position 2) is either a proline or an *N*-methylamino acid residue (see pp 59 to 65), and it has also been observed with a Gly-Gly-resin, as presented in detail in the forum discussion (pp 89 to 92).

It has been generally recognized that the less crosslinked polystyrene-1% divinylbenzene resin is a superior support compared to the 2% crosslinked material (see pp 221 to 224, 225 to 226). Unfortunately, the degree of crosslinking of commercially available resins is never accurately defined. Moreover, the chloromethylation reaction or prolonged storage in the presence of residual

catalyst can cause additional crosslinking. An approximate estimation of the degree of crosslinking could be obtained from the extent of resin swelling in solvents.

The incorporation of Boc-His(Bzl) by DCC mediated condensation is known to be accompanied by racemization.[1] This has been confirmed (pp 227 to 230); and ways to suppress this racemization were outlined in the discussion. Although addition of *N*-hydroxysuccinimide[1,2] lowers racemization, it can lead to the known β-alanyl peptide formation.[1,3] Good results were obtained by the addition of hydroxybenzotriazole.[4,5] Alternatively, racemization can be reduced to a few tenths of a percent by reducing the imidazole side chain basicity by tosyl or 2,4-dinitrophenyl protection. However, the tosyl group of Boc-His(Tos) is not very stable, and the thiol reagents employed for the N^{im}-Dnp group cleavage can in residual trace amounts interfere with subsequent hydrogenolytic reactions by poisoning the catalysts.

The development of the ring-halogenated benzyl protecting groups for more acid-stabile side chain blocking (pp 191 to 195, 197 to 202) apparently followed literature guidelines, such as σ-ρ diagram values.[6] Cleavage rates were determined with 50% trifluoroacetic acid in methylene chloride, and it was pointed out that cleavage by other acids should also be examined. A troublesome side reaction occurs with *O*-protected tyrosine during the final removal of the completed peptide from the solid support by treatment with HBr in TFA or with HF-anisole (1:1). *O*-Benzyltyrosine gives 13% of 3-benzyltyrosine by intramolecular rearrangement. The extent of this undesired rearrangement is lower (4%) with *O*-(2,6-dichlorobenzyl)tyrosine, but it could not be suppressed by modifications of the cleavage reagent or by addition of various scavengers (inorganic iodides, organic sulfides.)

The successful application of Mukaiyama's oxidation-reduction condensation[7] to solid-phase synthesis (pp 209 to 211) raised the question whether it would be suitable for peptide cyclization. This seemed to have not yet been investigated. The opinion was presented that the reaction might proceed *via* intermediate mercaptopyridine esters. These anchimerically catalyzed compounds do not suffer from strong overactivation; and the Boc group cleavage observed with DCC activation (*vide supra*) would be avoided in oxidation-reduction condensations.

The report on resin-bound *N*-ethyloxycarbonyl-2-ethyloxy-1,2-dihydroquinoline (EEDQ) as a regenerable solid-phase coupling reagent (pp 217 to 219) evoked the comment that

an ethyloxycarbonylamino derivative has been isolated as a by-product from an EEDQ-mediated peptide condensation[8] in solution. The formation of this type of side product is consistent with the intermediate mixed anhydride mechanism proposed by Belleau and Malek,[8] and a warning was sounded that this side reaction might also occur with the use of solid-phase EEDQ.

The presentations of three papers on the application of the solid-phase method to the preparation of biologically active peptides (lysozyme, LH-RH/FSH-RH, and valine gramicidins B and C; pp 231 to 250) were followed by arguments about alleged disparities between experimental results and the titles of some papers. One discussant placed the responsibility squarely upon the editor. My own opinion,[9] briefly, is:

Titles do imply claims of priority and achievement (especially since entire literature information systems are based on titles). The art and virtue of understatement should be practiced more often (compare titles in references 10, 11).

Synthesis, i.e. assembly of a molecule *identical* to a known structure, when done without characterization of each intermediate, as in solid-phase synthesis, requires meticulous examination of the final product to prove identity with the target structure.

Characterization of small peptides perhaps up to eicosapeptides, can in most cases be attained by a combination of amino acid and elemental analysis, thin layer chromatography in several solvent systems, tests for optical purity by ORD and enzymatic digestion, and demonstration of full biological activity, preferably by four-point assays of several different activities (if applicable). Additional data (IR, UV, NMR, mass spectrum) are desirable.

Large peptides or protein preparations necessarily require all the above tests but these are not sufficient. The rules for demonstrating homogeneity of a protein call for the examination of a minimum of five independent criteria (see *e.g.* [12]), such as peptide mapping, end group determination by dansylation and carboxypeptidase digestion, gel electrophoresis, isoelectric focusing in pH gradients[13] or in polyacrylamide gel,[14] rotating free zone electrophoresis,[15] sedimentation, distribution by countercurrent and chromatographic techniques, affinity chromatography, immunochemical tests, or functional purification by limited enzymatic digestion of enzyme-substrate complexes.[16]

In conclusion, it should be good to remember that researchers, not trained in peptide synthesis, are probably not aware of the problems. We have a responsibility of meticulously accurate reporting, and we must insist that the quality of work always conforms to the highest possible standards that can be attained with the newest available methods.

CHEMISTRY AND BIOLOGY OF PEPTIDES

SOLID-PHASE SYNTHESIS OF RIBONUCLEASE T_1

N. Izumiya, M. Waki, T. Kato, M. Ohno, H. Aoyagi, N. Mitsuyasu. Laboratory of Biochemistry, Faculty of Science, Kyushu University, Fukuoka, Japan

SUMMARY--Several preliminary experiments were carried out prior to the solid-phase synthesis of ribonuclease T_1. For example, the usefulness of hydrogen chloride in formic acid for the cleavage of *N*-*t*-butyloxycarbonyl groups has been demonstrated in a solid-phase synthesis of a tryptophan-containing model peptide. The Merrifield solid-phase method was used to prepare protein through 104 steps of amino acid incorporation following the target sequence of ribonuclease T_1. Purification of the protein preparation isolated from the protected peptide resin raised the specific nuclease activity up to 53% for yeast RNA and 41% for 2',3'-cyclic guanylic acid.

INTRODUCTION--The conventional methods of peptide synthesis have made many important and principal contributions to the solid-phase method of peptide synthesis (SPS). For example, many protecting groups and coupling reagents used in SPS are originating from conventional methods, such as *t*-butyloxycarbonyl (Boc), benzyloxycarbonyl (Z), benzyl ester (OBzl; including the peptide to resin linkage), *S*-benzyl, N^{im}-benzyl, N^{im}-(2,4-dinitrophenyl) (Dnp), dicyclohexylcarbodiimide (DCC), DCC plus *N*-hydroxysuccinimide (HOSu), *etc.* Contributions from SPS to conventional methods seem to be smaller, but the 2-(p-biphenylyl)isopropyloxycarbonyl group (Bpoc) and the liquid hydrogen fluoride reagent are notable contributions.

It is generally accepted that the solid-phase technique developed by Merrifield cannot at present be used for the confirmation of a proposed primary structure of a protein by synthesis.[1] However, it is well recognized that SPS possesses very attractive and useful features such as speed, simplicity, automation, *etc.* The purpose of our present investigations is outlined as follows.
(1) We intend to collect some information which might help to achieve a "clean" synthesis of a protein, perhaps by a conventional method or by a solid-phase fragment synthesis.[2] We plan to gain such information from the experimental results obtained during a stepwise solid-phase synthesis of a polypeptide with the target sequence of a known protein.
(2) New features which are developed during stepwise SPS will, it is hoped, contribute to improvements of conventional methods.

We have carried out stepwise solid-phase syntheses of basic pancreatic trypsin inhibitor (BPTI),[3] cobrotoxin (CT),[4] and ribonuclease T_1 (RNase T_1)[5] with the intentions mentioned above. In this presentation we describe the features of the solid-phase synthesis of RNase T_1 and also some experiments for improved protection of amino acid side chain functions.

Protection of Several Functional Side Chains

Although, at present, several combinations of protecting groups for functional side chains are available for SPS, we attempted to introduce new more effective protecting groups for some side chain functions.

Indole moiety in tryptophan*

It is well known that tryptophan in a peptide chain being synthesized on a polymer support undergoes oxidation during treatment with HCl in AcOH for the cleavage of Boc groups. In such cases, β-mercaptoethanol (βME) or dithiothreitol[6] have been used as a scavenger to protect tryptophan. Previero *et al.*[7] observed that bubbling of HCl into formic acid (HCOOH) solutions of tryptophan results in formylation of the indole nitrogen (N^1). We

*RNase T_1 and CT (possessing 62 amino acid residues) have only one tryptophan residue each in positions 59 and 29, respectively, and BPTI (58 residues total) has no Trp.

found that tryptophan and N^I-CHO-Trp-OH are stable in 0.1-1.0 *N* HCl-HCOOH; the Boc group is cleaved rapidly with a 2-10 fold molar excess of HCl in HCOOH, and the N^I-formyl group is removed by 0.1 *N* aqueous piperidine or hydrazine in DMF although this group is not influenced by triethylamine in DMF or by HF. These observations led us to examine HCl-HCOOH as a reagent for cleaving Boc groups in SPS of tryptophan-containing peptides.

As an example, a 6-fold molar excess of HCl (0.1 *N*) in HCOOH was used in the synthesis of a model peptide, H-Lys-Ala-Gly-Leu-Gly-Trp-Leu-OH, which was built up by SPS in the usual way.[8] In parallel, two peptides with the same sequence were prepared using 1 *N* HCl-AcOH in the presence and absence of βME (2%).

One half of each protected peptide-resin was cleaved by hydrazinolysis, and the three products corresponding to Boc-Lys(Z)-Ala-Gly-Leu-Gly-Trp-Leu-$NHNH_2$ were isolated; they were designated as Ia (HCl-HCOOH), Ib (HCl-AcOH-βME), and Ic (HCl-AcOH), respectively. The UV spectrum of Ia was virtually identical with that of Z-Trp-OH. Extinction coefficients of Ib and Ic at 282 nm were 34% and 45% more intense than that of Ia, respectively. Such enhancement at 282 nm should be ascribed to oxidation of the indole nucleus although the side products formed have not yet been identified.

The other halves of the protected peptide-resins were treated with HF, and the peptide (IIa) produced *via* the HCl-HCOOH procedure was further treated with 0.1 *N* aqueous piperidine to remove the N^I-formyl group. Each product was chromatographed on a column of Sephadex G-25; IIb (synthesized *via* the HCl-AcOH-βME procedure) gave a complex elution profile due to its heterogeneity, whereas that from IIa gave a simple profile with one major peak. To ascertain whether the major peak from IIa is based only on pure peptide, IIa was treated with 2-nitro-4-carboxy-phenylsulfenyl chloride (Ncps-Cl) in 80% HCOOH. The modified peptide was again chromatographed on the same column, and gave one peak at a different, delayed position. This showed that the modified peptide containing 2-thio-(2-nitro-4-carboxyphenyl)-tryptophan possessed, as expected, an increased absorptivity to the gel compared to the unmodified peptide. It is apparent from these results that the original peptide in the major peak from IIa contains only pure (unoxidized) tryptophan. Comparison of the two elution diagrams before and after reaction of IIb with Ncps-Cl indicates that IIb contains some material in

which the tryptophan residue had suffered changes from the repeated HCl-AcOH-βME treatments.

We think that more experiments are required before the HCl-HCOOH system can be applied to SPS of macropeptides such as RNase T_1. We are performing the SPS of the naturally occurring decapeptide LH-RH which contains one tryptophan, as a model experiment to gain further experience with the HCl-HCOOH procedure. In the SPS of RNase T_1 reported herein we still used the usual 1 *N* HCl-AcOH-βME (1%) reagent and Boc-Trp-OH under complete replacement of air by N_2 gas. With respect to our intentions in the present studies, the HCl-HCOOH system developed during the SPS experiments is now being routinely applied in conventional syntheses in our laboratory. For example, crystalline H-Orn(Z)-Leu-OEt·HCl has been obtained from Boc-Orn(Z)-Leu-OEt by treatment with 0.1 *N* HCl (1.2 equiv) in HCOOH for 10-20 min; the Z group is more stable in 0.1 *N* HCl-HCOOH than in HCl-dioxane or CF_3COOH.

Phenol moiety in tyrosine

In SPS, Boc-Tyr(Bzl)-OH has been used usually, however, the phenolic benzyl ether linkage is relatively resistant to HF.[9] Stewart and Young suggested in their monograph[10] the use of *p*-methoxybenzyl ether which might be removed easily by HF. We prepared crystalline Boc-Tyr(MeOBzl)-OH *via* the following sequence of reactions. Tyrosine copper complex was treated with *p*-methoxybenzyl chloride which was prepared from anisalcohol and PCl_3. The Tyr(MeOBzl)-Cu complex was decomposed with EDTA and the resulting H-Tyr(MeOBzl)-OH was treated with Boc-N_3. We found, however, that the *p*-methoxybenzyl ether linkage of Boc-Tyr(MeOBzl)-OH is more resistant to cleavage by hydrogen fluoride than the benzyl ether (see Table I). Therefore, Boc-Tyr(Bzl)-OH was used in the SPS of RNase T_1. Conditions were developed to achieve practically complete cleavage of the benzyl ether linkage, as described later.

Imidazole moiety in histidine

In the SPS of histidine-containing peptides the N^{α}-Boc derivatives of N^{im} unprotected His, His(Z), His(Dnp), His(Boc),[6] His(Tos)[11] *etc.* have been applied. We used Boc-His(Boc)-OH in the SPS of RNase T_1 because of its greater solubility in organic solvents and its ease of preparation, although Boc-His(Tos)-OH seemed to be a promising starting material as well.

Table I

Cleavage of Protecting Groups of Tyrosine by Liquid Hydrogen Fluoride

Compound	*0°C*		*20°C*
	0.5 hr	*1 hr*	*1 hr*
Boc-Tyr(Bzl)-OH	---	70-75%	95-98%
Boc-Tyr(MeOBzl)-OH	30%	33-40%	90%

Besides stepwise SPS of RNase T_1, we are also attempting solid-phase fragment condensation, but the present work is of very preliminary status. We prepared three Boc-peptide acids (III, IV, V)[12] and try to assemble them on the polymer support by DCC plus HOSu, or by EEDQ. For the preparation of V, Boc-Val-Ile-Thr(Bzl)-His-Thr(Bzl)-Gly-OH (VI) was tosylated to give crystalline V in a good yield, whereas benzyloxycarbonylation or dinitrophenylation of VI resulted in a poor yield or in the formation of colored material.

Preliminary Experiments Prior to the Solid-Phase Synthesis of Ribonuclease T_1

RNase T_1 was isolated from *Aspergillus oryzae* by Egami in 1957,[13] and its amino acid sequence of 104 residues was determined by Takahashi in 1965,[14] Figure 1. The enzyme is an acidic protein (pI 2.9) and has two intramolecular disulfide bonds. Hofmann has been working on the total synthesis of this protein by conventional methods.[15] We are carrying out a synthesis of protein with the target sequence of RNase T_1 by stepwise SPS,[5] besides syntheses

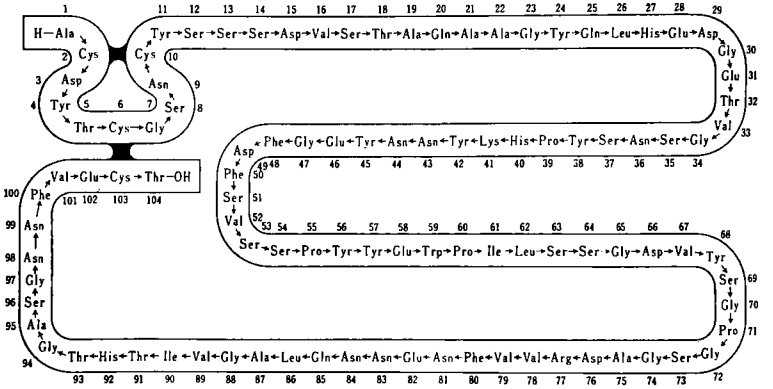

Figure 1: The primary structure of ribonuclease T_1.

of several short fragments through conventional methods[16] and making arrangements for fragment SPS.[12] Prior to the stepwise SPS, we performed the following experiments.

Treatment of natural RNase T_1 with liquid hydrogen fluoride

Since it is planned to treat the final, fully protected peptide-resin in the SPS with HF, it is important to examine the stability of natural RNase T_1 to HF treatment. The natural enzyme* (220 μg, 0.02 μmol) was treated with HF (0.5 ml) in the presence and absence of tryptophan. After certain time intervals, the solution was evaporated and the residue was tested for RNase T_1 activity using yeast RNA as a substrate. The results are summarized in Table II and show recovery of 80-90% activity after 1 hr at 0° in the presence of added tryptophan and about 75% after 3 hr.

Treatment of some Boc-amino acids with liquid hydrogen fluoride

For the incorporation of tyrosine residues, Boc-Tyr(Bzl)-OH was selected for the SPS of RNase T_1, as mentioned before. Since the N^{ε}-Z group of Boc-Lys(Z)-OH is cleaved gradually

---

*Obtained from Sankyo Company.

Table II

Residual Activity (%) of RNase T_1 After Treatment with Liquid Hydrogen Fluoride

Trp added, in equiv	*0°C*			*20°C*	
	1 hr	*3 hr*	*4 hr*	*1 hr*	*2 hr*
---	77	57		38,33	43
125	92		47		
250	82	76		35	

by successive treatments with HCl-AcOH or CF_3COOH, we chose Boc-Lys(Dipmoc)-OH. Sakakibara introduced the Dipmoc (diisopropylmethyloxycarbonyl) group into SPS. This group is cleaved by HF but very stable to 1 *N* HCl-AcOH.[17] Our results with HF are summarized in Table III.

Table III

Cleavage (%) of Side Chain Protecting Groups by Liquid Hydrogen Fluoride

Compound	*0°C*		*20°C*
	1 hr	*3 hr*	*1 hr*
Boc-Tyr(Bzl)-OH	70-75	95-97	95-98
Boc-Lys(Dipmoc)-OH	78-80	98-100	~100

From the results indicated in Tables II and III, we selected as optimal conditions of HF treatment a temperature of 0°C and a duration of 3 hr for the deprotection of a fully protected peptide-resin. However, it should be noted that some protecting groups in the protected peptide-resin may be incompletely cleaved by HF even after 3 hr, possibly, because some may be buried inside and cannot contact freely with HF.

The Stepwise Solid-Phase Synthesis of Ribonuclease T_1

We carried out the stepwise SPS of RNase T_1 as usual. Since the procedure is similar to that employed in solid-phase syntheses of BPTI[3] and CT,[4] we describe the course and the present status of our experiments only briefly.

SPS procedure

Commercial 2% cross-linked polystyrene was chloromethylated in the usual manner, and a resin containing 1.46 mmol/g of Cl was obtained. This was converted to HCl·H-Thr(Bzl)-resin with 0.21 mmol/g of threonine. Two parallel runs of the SPS of manual way were made for syntheses of Boc-peptide-resin of 104 amino acid residues, one with the sequence by natural RNase T_1 and the other with that of an analog, [Tyr^{59}]-RNase T_1. The schedule of a cycle for the incorporation of each Boc-amino acid was almost the same as described before[3,4] with the exception of the use of Lys(Dipmoc) and His(Boc). 1.3 *N* HCl-AcOH was used as a cleaving reagent for Boc groups. After the incorporation of tryptophan in position 59, 1% βME was added to the 1.3 *N* HCl-AcOH reagent and also to the AcOH washing solvent, and air in the reaction vessel was completely replaced by N_2 gas. Yields of the fully protected peptide-resins are summarized in Table IV along with the results of the BPTI and CT preparations.

Table IV

Yield of Protected Peptide-resins

Synthetic object	*Starting HCl·amino acid-resin*	*Completed protected peptide-resin*	*Yield (%)*		
			Weight increase	*Cl titration*	*Amino acid analysis*
RNase T_1	3.8 g	10.3 g	53	56	55
[Tyr^{59}]-RNase T_1	1.9 g	4.8 g	49	49	51
Trypsin Inhibitor (BPTI)	1.0 g	1.3 g	20		
Cobrotoxin	2.4 g	4.4 g	39		

Isolation of peptide from protected peptide-resin

Cleavage of the polypeptides from the solid support together with the removal of all protecting groups was achieved by treatment with HF in the presence of anisole. The procedure of Exp. B (see Table V) is described as follows. After evaporation of HF and drying *in vacuo*, the

Table V

Treatment of Peptide-resin with Liquid Hydrogen Fluoride* at 0°C and Yields of Crude Peptides

	RNase T_1			*Basic Pancreatic Trypsin Inhibitor*	*Cobrotoxin*
	Exp.

Protected Peptide-resin	0.163 g	1.0 g	0.5 g	0.5 g	0.5 g
Time of HF treatment*	1 hr	3 hr with Trp		1 hr	1 hr
Extraction solution	Tris-HCl, pH 7.0	NH_4HCO_3, pH 8.0		10% AcOH	5% AcOH
Amount of crude peptide	6 mg	180 mg	78 mg	31 mg	55 mg
(Yield)	(8%)	(39%)	(34%)	(31%)	(36%)

*Anisole was added.

residue was washed with acetone containing 2% 1*N* HCl to remove anisole. To the residue, a mixture (pH 8.0) of 0.05 *M* NH_4HCO_3 and 0.1 *M* NaCl was added. The whole mixture was subjected to air oxidation for generating disulfide bonds. The filtrate from the resin was lyophilized and dialyzed. The solution was passed through a column of Sephadex G-50, and fractions containing proteins were lyophilized. The yield of crude peptide was 180 mg (39% from peptide-resin). Yields of crude peptides in three experiments are summarized in Table V.

Purification of crude peptide

The product of Exp. A was purified as follows. The crude peptide (6 mg; see Table V) was chromatographed on a column (0.9 x 38 cm) of Sephadex G-75 with 0.02 *M* NH_4HCO_3 (pH 7.5) as an eluant. A major peak gave 2.4 mg of a protein with a specific activity (SA) of 0.4%. This protein was treated again in similar manner; yield 0.8 mg, SA 1.1%. Further chromatography gave 0.45 mg protein with SA 2.2%.

The protein (0.45 mg), treated three times with G-75, was further chromatographed on a column (0.9 x 8 cm) of DEAE cellulose in a manner of linear-gradient elution with 0.005 *M* Na_2HPO_4-0.25 *M* $Na_2H_2PO_4$, 0.25 *M* NaCl. A main peak afforded 0.16 mg of a protein with SA 23%.

The protein (0.16 mg) obtained was incubated with chymotrypsin (0.016 mg) at pH 7.0 and 37°C for 15 hr. After salts in the incubation mixture were removed by Sephadex G-50 chromatography, the eluate was chromatographed on a column of DEAE cellulose; the yield was 0.09 mg and SA was 53%[5] for yeast RNA and 41% for guanosine 2',3'-cyclic phosphate.

Conclusion

Many parts of our studies have apparently not yet been completed. Furthermore, it is questionable whether a protein with 53% or 41% activity of RNase T_1 contains molecules identical to natural RNase T_1. Nevertheless, our experiments may provide some useful information for a future "clean" synthesis of RNase T_1 and its analogs.

Acknowledgment

The authors express their thanks to Mr. S. Terada and Mr. S. Matsuura for technical assistance.

CHEMISTRY AND BIOLOGY OF PEPTIDES

ON THE SYNTHESIS OF A PORCINE GASTRIC INHIBITORY POLYPEPTIDE

R. Camble. Imperial Chemical Industries Limited, Pharmaceutical Division, Alderley Park, Macclesfield, Cheshire, England.

"GASTRIC INHIBITORY POLYPEPTIDE" (GIP) was isolated from commercially available, partially purified cholecystokinin.[1] It is reported to be a potent inhibitor of both histamine and pentagastrin stimulated gastric acid and pepsin secretion in the dog;[2] as such, it could be the "enterogastrone" released from the duodenum by fat. The peptide is a single chain of 43 amino acid residues containing no disulphide bridges.[3] The N-terminal region shows considerable homology with the sequences of glucagon and secretin. Dr. Brown kindly provided us with details of the structure prior to publication and as part of a continuing investigation into natural inhibitors of gastric secretion[4] we undertook a synthesis of GIP. This communication is a report of our progress towards that goal. Our approach involved the preparation by stepwise elongation of seven protected fragments (Figure 1). These are to be linked by azide or mixed anhydride reactions to give the complete molecule.

Preparation of the fragments

The fragments were chosen for obvious chemical reasons and from a desire to pursue any indication of a biologically active core. Fragments C, D, E, F and G were built up with *t*-alkyl side chain protection and the benzyloxycarbonyl group was used for α-amino group protection. In fragment B the N-terminal methionine residue was introduced as its *N-o*-nitrophenylthio derivative. For fragment A, side chains were blocked as their benzyl derivatives and the *t*-butoxycarbonyl group was employed for α-amino protection.

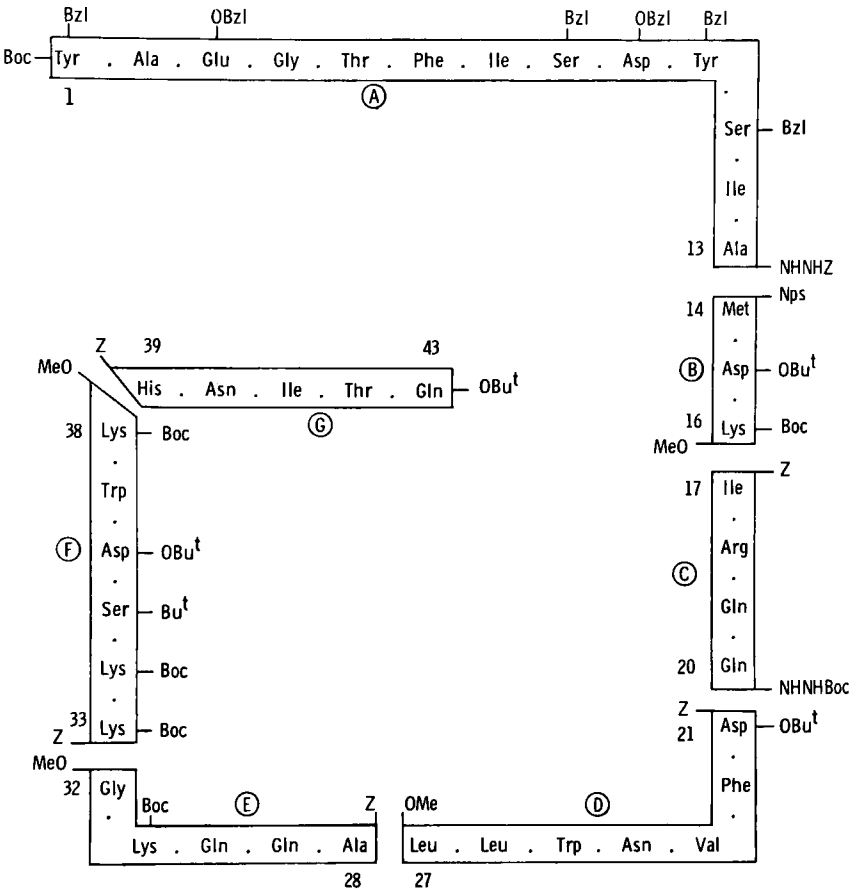

Figure 1: **Sequence and protected peptide fragments for the synthesis of gastric inhibitory polypeptide.**

The presence of up to six side chain benzyl groups during the synthesis of fragment A made the coupling products very insoluble and tlc was of little use as a check for purity after the octapeptide stage. The BOC-tridecapeptide hydrazide, obtained after prolonged hydrogenolysis of fragment A over spongy palladium or 5% palladium on charcoal, exhibited four major components on tlc. These appear to arise from incomplete removal of the benzyl protecting groups. (Resistance of the serine O-benzyl derivative to hydrogenolysis has been observed in work on LRF synthesis in our laboratory[5]). We hope to employ this material for further coupling and to remove any remaining benzyl groups by acid treatment at the end of the synthesis.

The o-nitrophenylthio group was removed from fragment B with 80% thioglycollic acid[6] and the product was purified by silica gel and Bio-Rex 70 (H^+ cycle) column chromatography.

To minimize the risk of rearrangement of the N-terminal aspartic acid residue of fragment D[7] the β-*t*-butyl ester was removed before treatment with hydrazine. Hydrazinolysis of fragments D and F in DMF solution was slow even with large excesses of hydrazine.[8] Much faster reaction rates were obtained by using DMF-*n*-butanol (1:1) as solvent.[9]

When the well-characterized fragment E was treated with alkali in aqueous DMF a complex mixture was always obtained. The desired product was isolated in about 35% yield after chromatography on AG1-X2 (acetate cycle) anion exchange resin;[10] from their elution pattern the impurities appeared to be more acidic than the product and emerged at two distinct concentrations of acetic acid. NMR, hydrogenolysis and amino acid analysis results on the impurity fractions suggested that, in addition to any possible rearrangement and deamidation of the glutamine residues, the N-terminal benzyloxycarbonylalanine residue must have rearranged extensively to the corresponding hydantoin.

The five *t*-butyl derivatives were not removed cleanly from fragment F by aqueous trifluoroacetic acid. An acceptable product was obtained after reaction with HBr-trifluoroacetic acid. This observation was disappointing as it probably nullifies the idea behind the approach used for the synthesis of fragment A.

Fragment couplings and assessment of purity

The task of joining up the fragments has progressed to the point shown in Figure 2. The properties of the products were such that, until the heptacosapeptide stage, purification was limited to selective precipitation and chromatography

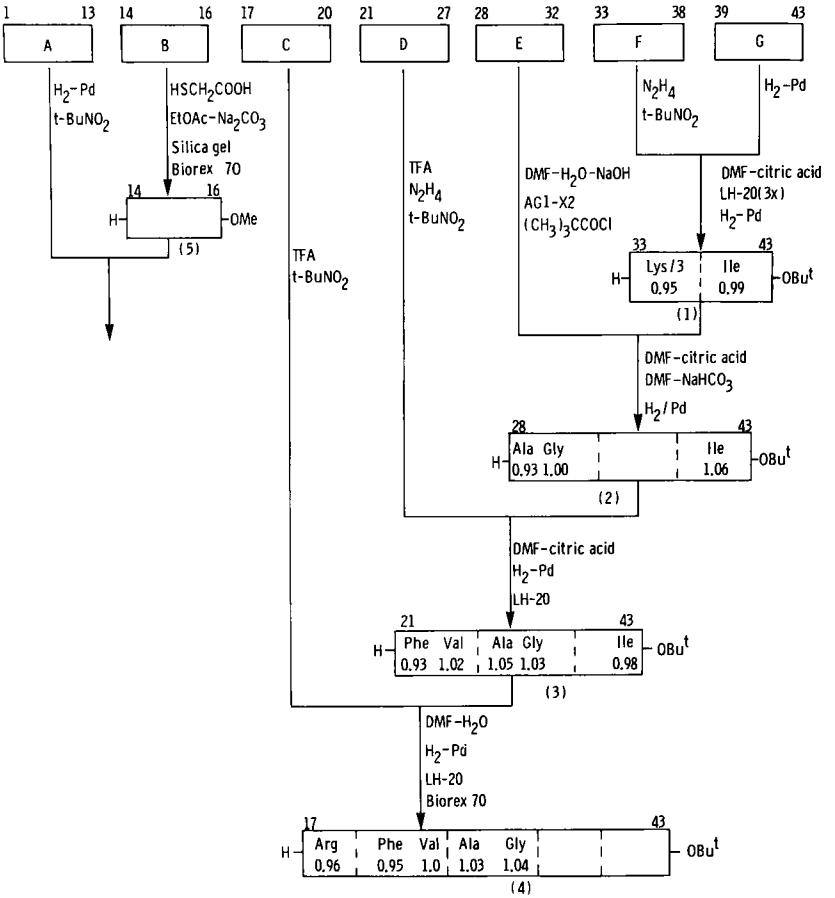

Figure 2: **Fragment condensation steps toward the synthesis of gastric inhibitory polypeptide.**

on LH-20 Sephadex in DMF solution. Purity was assessed by tlc and the ratios between 'diagnostic' amino-acid residues.[11] Tlc was of limited use with the heptacosapeptide and arginine was the only diagnostic residue in the N-terminal portion. At this point we began to exploit the non-quantitative but extremely sensitive dansylation technique[12] as an additional test of purity. About 4 nanomoles of the almost ninhydrin negative heptacosapeptide derivative (4) gave a very intense dansyl-isoleucine spot but no dansyl-aspartate or ε-dansyl-lysine. Dansylation of (4) following treatment with 90% trifluoroacetic acid generated both dansyl-isoleucine and ε-dansyl-lysine after hydrolysis. Backtracking, the hexadecapeptide derivative (2) gave only dansyl-alanine. In spite of an excellent ratio of diagnostic amino-acids, the tricosapeptide derivative (3) produced a faint but definite trace of dansyl-alanine as well as the expected dansyl-aspartate. The technique was also employed to confirm that the purified tripeptide (5) contained no free lysine ε-amino group after the thioglycollic acid treatment used to remove the *o*-nitrophenylthio group.

The value of diagnostic amino-acid ratios is critically dependent upon evidence, usually provided by tlc, that one of the two components in the coupling has been completely eliminated. Dansylation offers an additional and extremely sensitive tool with which to attack this problem of evaluating the purity of large synthetic peptide intermediates.

The synthetic team involved in this work comprised R. Camble, R. Cotton, A. Dutta, J. J. Gormley, C. F. Hayward, J. S. Morley and M. J. Smithers. Dansylation experiments were carried out by Mrs. B. M. Preston. Amino acid analyses were performed by M. W. Earlam.

CHEMISTRY AND BIOLOGY OF PEPTIDES

ON THE PROINSULIN SYNTHESIS

Noboru Yanaihara, Chizuko Yanaihara, Tadashi Hashimoto, Masanori Sakagami, Naoki Sakura. Laboratory of Bioorganic Chemistry, Shizuoka College of Pharmacy, Shizuoka, Japan

PORCINE PROINSULIN[1,2] is a single chain polypeptide which consists of eighty-four amino acid residues, and three disulfide bridges are present in the molecule. It has been demonstrated[3,4] that the reduced proinsulin reconstitutes the proper disulfides efficiently to restore the characteristic properties of native proinsulin. The connecting peptide segment of this prohormone connects the carboxy terminus of the B chain to the amino terminus of the A chain of the insulin molecule.

We have achieved previously the syntheses of [33-glutamine,62-formyllysine]porcine proinsulin 31-63[5] and [62-formyllysine]-porcine proinsulin 31-63[6] with the amino acid sequence of porcine connecting peptide segment. These synthetic tritriacontapeptides were found to possess immunological properties identical to those of natural connecting peptide fragment.[6] Synthesis of these polypeptides was performed essentially by the fragment condensation according to the modification of the azide method developed by Honzl and Rudinger.[7]

In a previous communication,[6] we have described briefly the synthesis of a partially protected linear octahexacontapeptide (I), Figure 1, possessing the 17 - 84 amino acid sequence of porcine proinsulin, together with its immunological properties.

The present article describes the strategies and current investigations on our studies aiming at the synthesis of porcine proinsulin. As reported previously,[6] the azide

Table I

Protected Peptide Fragments used for the Preparation of Proinsulin Fragments II and III

(A)	Z-Leu-Val-Cys(Ec)-Gly-NHNHBoc (positions 17-20)
(B)	Z-Glu(OBu^t)-Arg-Gly-Phe-Phe-Tyr-Thr-Pro-Lys(CHO)-Ala-NHNHBoc (positions 21-30)
(C)	Z-Arg(NO_2)-Arg-Glu-Ala-Glu(OBu^t)-Asn-Pro-Gln-Ala-Gly-NHNHBoc (positions 31-40)
(D)	Z-Ala-Val-Glu(OBu^t)-Leu-Gly-Gly-Gly-Leu-Gly-NHNHBoc (positions 41-49)
(E)	Z-Gly-Leu-Gln-Ala-Leu-Ala-Leu-Glu(OBu^t)-Gly-NHNHBoc (positions 50-58)
(F)	Z-Pro-Pro-Gln-Lys(CHO)-Arg-Gly-Ile-Val-Glu(OBu^t)-Gln-NHNHBoc (positions 59-68)
(G)	H-Cys(Ec)-Cys(Ec)-Thr-Ser-Ile-Cys(Ec)-Ser-Leu-Tyr-Gln-Leu-Glu-Asn-Tyr-Cys(Ec)-Asn-OH (positions 69-84)

condensation of protected tritriacontapeptide hydrazide (II) (positions 17-49) with partially protected pentatriacontapeptide (III)(positions 50-84), followed by treatment with hydrogen bromide in trifluoroacetic acid, resulted in the formation of I. The seven peptide fragments shown in Table I were employed for the construction of II and III. The benzyloxycarbonyl group was used as α-amino protecting group; ε-Amino groups of two lysine residues (positions 29 and 62) were protected with the formyl function, and the side chains of glutamic and aspartic acids were protected as *t*-butyl ester. The side chain of cysteine was blocked by the ethylcarbamyl(Ec) function.[8] The terminal carboxyl functions of six protected peptide fragments A to F were protected with *t*-butoxycarbonylhydrazide. On introduction of arginine into a peptide chain, the guanido function of this amino acid was protected with the nitro group. Syntheses of these protected peptide fragments were performed according to a strategy similar to that used for the synthesis of the peptide derivatives related to ribonuclease T_1.[9-12]

A variety of protected peptide derivatives terminating with glutamine-*t*-butoxycarbonylhydrazide were prepared as intermediates for preparation of the desirable peptide fragments. Examples are Z-Gly-Leu-Gln-NHNHBoc (positions 50-52), Z-Pro-Pro-Gln-NHNHBoc (positions 59-61), Z-Ile-Val-Glu(OBu^t)-Gln-NHNHBoc (positions 65-68) and Z-Cys(Ec)-Ser-Leu-Tyr-Gln-NHNHBoc (positions 74-78). Using the hydrazides derived from these protected intermediates, the glutamine moiety was introduced *via* azide coupling into the peptide chain smoothly without risk of lactam formation. The porcine proinsulin molecule contains eleven glycine residues, of which ten are located in the 17-84 sequence. Four glycine moieties were used as carboxy terminal amino acids of benzyloxycarbonyl peptide *t*-butoxycarbonylhydrazides. Glycine-terminating protected di- or tripeptides such as Z-Glu(OBu^t)-Arg(NO_2)-Gly-OH (positions 21-23), Z-Leu-Gly-OH (positions 44-45), Z-Gly-Gly-OH (positions 46-47) and Z-Lys(CHO)-Arg(NO_2)-Gly-OH (positions 62-64) were also prepared and their mixed anhydrides served as acylating agents.

For removal of benzyloxycarbonyl groups catalytic hydrogenolysis was conducted. This process also permitted simultaneous removal of nitro group on arginine residues. Benzyloxycarbonyl groups of cysteine-containing peptides were removed by treatment with hydrogen bromide in trifluoroacetic acid and anisole. By this treatment, *t*-butyl groups were also removed, while ethylcarbamyl and formyl groups were unaffected.

The final coupling in the preparation of I was accomplished by the formation of a linkage between positions 49 and 50, at both of which positions glycine moieties are located. In the synthesis of porcine connecting peptide,[5] we carried out the azide coupling of the hydrazide derived from fragment D (positions 41-49) with a tetradecapeptide (positions 50-63) and obtained a protected tricosapeptide (positions 41-63) in 63% yield. This indicates that the azide coupling of a peptide terminating with glycine at position 49 with a glycyl peptide such as pentatriacontapeptide III (positions 50-84) may take place efficiently under the reaction condition employed. Furthermore, we have planned to characterize our synthetic polypeptides by utilizing immunological properties specific to porcine connecting peptide and proinsulin, in addition to the usual analytical methods. Our studies[6] in cooperation with Drs. R. E. Chance and M. A. Root of the Lilly Research Laboratories have indicated clearly that the antigenic determinant in the porcine connecting peptide segment is located in the 41-54 sequence, -Ala-Val-Glu-Leu-Gly-Gly-Gly-Leu-Gly-Gly-Leu-Gln-Ala-Leu-. All synthetic and natural connecting peptide fragments containing this 41-54 sequence cross-reacted with the purified anti-porcine proinsulin antiserum on essentially equimolar basis, while the smaller synthetic nonapeptide (positions 41-49), pentapeptide (positions 50-54), and an equimolar mixture of these two peptides did not cross-react with the antiserum at all. In addition, it was found with the antiserum elicited by our synthetic connecting peptide[6] that synthetic connecting peptide is displaced by natural porcine proinsulin on an equimolar basis, while synthetic nonapeptide (positions 41-49) and tetradecapeptide (positions 50-63) do not react. Thus, none of the polypeptide fragments used for the preparation of I embodies the amino acid sequence that corresponds to the antigenic determinant, the 41-54 sequence. If the coupling of II with III results in the formation of the desired linkage between positions 49 and 50, the ensuing polypeptide embodies the 41-54 sequence and must be immunologically reactive.

Indeed, our synthetic partially protected polypeptide I cross-reacted with anti-synthetic porcine connecting peptide antiserum. The cross-reactivity of I was essentially as high as that of natural porcine proinsulin or synthetic porcine connecting peptide, indicating the successful formation of the desired linkage between positions 49 and 50. The amino acid compositions of I were those predicted by theory. Purification of I, II and III were conducted

exclusively by gel filtration, because of the low solubility of these polypeptides in buffers for column chromatography.

Synthesis of protected hexadecapeptide hydrazide (positions 1-16) has been described.[6] Continuous investigation for the total synthesis of porcine proinsulin is under way.

CHEMISTRY AND BIOLOGY OF PEPTIDES

CRYSTALLIZATION OF SYNTHETIC POLYPEPTIDES WITH TRIPLE-HELICAL STRUCTURE

Shumpei Sakakibara, Yasuo Kishida, Saburo Aimoto.
Peptide Institute, Protein Research Foundation,
Minoh, Osaka, Japan

TWO OF US (S.S. AND Y.K.) AND OTHERS[1] have previously reported the synthesis of a new kind of sequential polypeptide of the structure $(Pro\text{-}Pro\text{-}Gly)_n$ (n = 10 or 20) using the fragment condensation technique on the Merrifield resin. These polypeptides are homogeneous in molecular weight and they have physical properties similar to collagen. The polymers are soluble in aqueous acetic acid and aqueous ethanol, but less soluble in distilled water. In dilute aqueous acetic acid these polypeptides show an optical rotation change, as shown in Figure 1, which accompanies a three fold change in molecular weight.[2] Thus, this rotation change was attributed to a transition between triple-helix and coil. Below 10°C and in high concentrations those triple-helical molecules form microcrystalline segments similar to the fibrous long-spacing segments of collagen; this phenomenon was confirmed by electron microscopy.[3]

Recently, we have found that the polypeptide $(Pro\text{-}Pro\text{-}Gly)_{10}$ gave single crystals under specific conditions.[4] We report herein the procedure for the crystallization and an attempt to incorporate a bromine atom into each molecule in order to facilitate X-ray analysis of the structure.

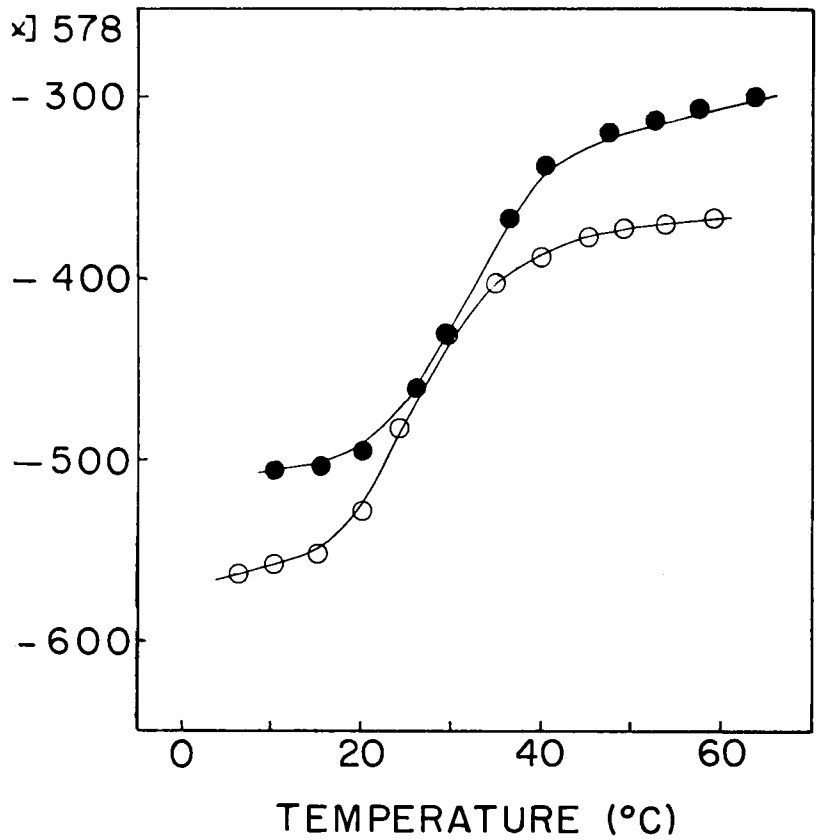

Figure 1: Temperature-dependence of specific rotation in 10% acetic acid at 578 mμ:
(○) $(Pro\text{-}Pro\text{-}Gly)_{10}$;
(●) $Pro(4Br)\text{-}Pro\text{-}Gly\text{-}(Pro\text{-}Pro\text{-}Gly)_9$.

Crystallization of $(Pro\text{-}Pro\text{-}Gly)_{10}$

A 5% solution of the amorphous polymer in 10% aqueous acetic acid was sealed in a cellophane tube and dialyzed against distilled water at a temperature below 10°C. The dialysis was carried out in a tight cylinder with a stopcock at the bottom to control the speed of the release of acetic acid. When the pH of the outside solution reached 4.7, the flow rate of distilled water was adjusted to about one drop per second. Fine crystals appeared on the inner surface of the cellophane bag when the pH of the effluent

reached 5.2. Dialysis was continued overnight under the same conditions and crystals with a maximum edge of about 0.25 mm were collected by filtration with 60% recovery. Crystallization could also be induced when amorphous polymer was dissolved in distilled water at 40°C followed by lowering the temperature to 10°C and seeding, but almost all crystals so obtained were imperfect for X-ray analysis. Since these molecules are distributed as individual triple-helices in aqueous acetic acid at 10°C, crystallization by the dialysis method proceeds smoothly with decreasing acetic acid concentration. In the cooling method, however, both triple-helix formation and aggregation of helices have to take place during the same process; therefore, packing of helical molecules in crystals may not be as regular.

One crystal obtained by the dialysis method was examined by X-ray diffraction, and it was confirmed that the crystal is orthorhombic with unit cell dimensions of a=26.9, b=26.4 and c (fiber axis)=100.4 Å. The amount of absorbed water in crystals was determined to be about 50% by measuring the decrease of the weight during drying at 80°C over P_2O_5 *in vacuo* for 5 hours. On the basis of the observed water-content and crystal density (1.31 $g \cdot cm^{-3}$), X-ray crystallographers of our group suggested that the unit cell consists of twelve chains of $(Pro\text{-}Pro\text{-}Gly)_{10}$ which may be arranged in four triple-helical structures. They arrived at a tentative electron density map projected along the c-axis as shown in Figure 2; the main peak may be a triple-helix of $(Pro\text{-}Pro\text{-}Gly)_{10}$. Details of the X-ray study will be published elsewhere.

Incorporation of bromine atom in polypeptide chain

In order to facilitate the X-ray analysis of the crystal structure, incorporation of a bromine atom in each N-terminal prolyl residue was attempted. First, 4-bromo-L-proline was synthesized as follows: N-benzyloxycarbonyl-L-hydroxyproline benzyl ester was treated with freshly prepared PBr_5 at 0°C in methylene chloride. Then, the brominated product was treated with anhydrous HF under standard condition to remove the protecting groups.[5] Finally, 4-bromo-L-proline was isolated from the reaction mixture by counter-current distribution using the solvent system *n*-butanol-acetic acid-water (4:1:5,v/v/v). Total yield of purified 4-bromo-L-proline was about 30%; m.p. 201.5°C. (decomp.), $[\alpha]_D^{24}$ - 19.3° (c 1.1, water). This amino acid was converted to the *t*-amyloxycarbonyl

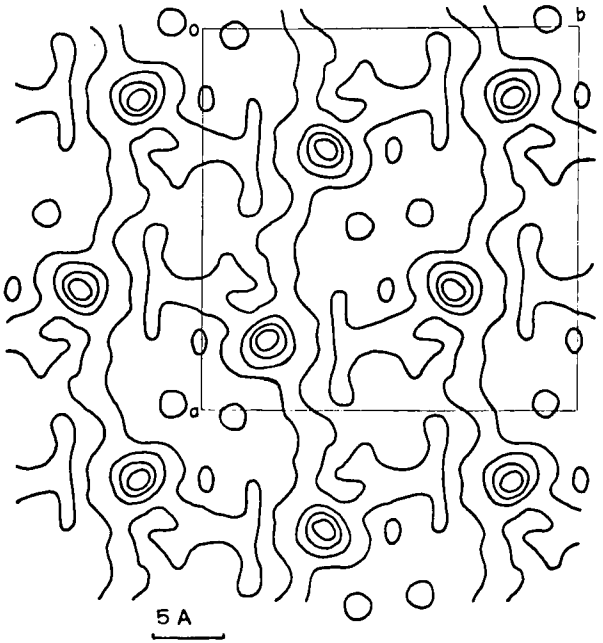

Figure 2: A tentative electron density map projected along the *c*-axis.

derivative, which was then coupled with Pro-Gly-(Pro-Pro-Gly)$_9$-Resin prepared from an intermediate for the synthesis of (Pro-Pro-Gly)$_{10}$.[1] The product was isolated from the resin using the HF method as in the case of the synthesis of (Pro-Pro-Gly)$_{10}$. The physical properties of the bromine-containing polymer in aqueous solution were found to be similar to those of the original polymer; the optical rotation change in aqueous acetic acid is shown in Figure 1.

Crystallization of this polymer was attempted by the dialysis method, and it was found that crystallization of the brominated polymer was even better than that of the original polymer. Crystals obtained were as big as 0.8 x 0.8 x 0.3 mm^3, (Figure 3). X-Ray studies with these crystals are under way.

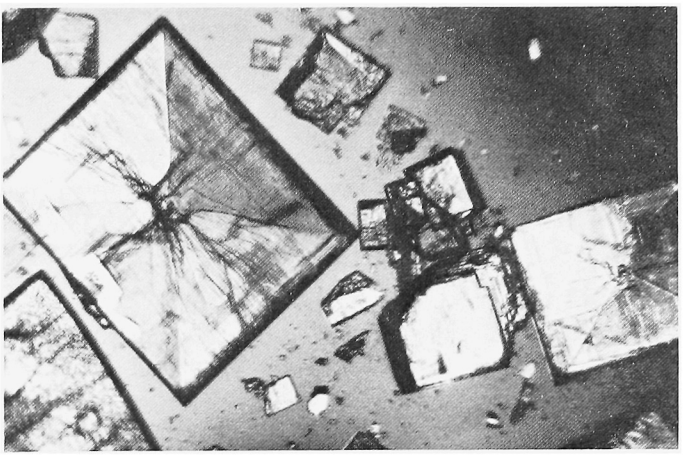

Figure 3: Single crystals of Pro(4Br)-Pro-Gly-(Pro-Pro-Gly)$_9$ viewed under the polarized microscope. A maximum edge is about 0.8 mm long.

Acknowledgment

The authors express their gratitude to Professor Masao Kakudo of Osaka University and his colleagues for their skillful cooperation in X-ray analysis of these crystals.

CHEMISTRY AND BIOLOGY OF PEPTIDES

A NOVEL METHOD FOR THE SYNTHESIS OF LONGER PEPTIDES INCLUDING THE CORRECTED STRUCTURE OF HUMAN ACTH AND ITS FRAGMENTS

L. Kisfaludy, M. Löw, T. Szirtes, I. Schön, M. Sárközi.
Chemical Works of Gedeon Richter Ltd., Budapest, Hungary

K. Medzihradszky. Institute of Organic Chemistry, Eötvös University Budapest, Budapest, Hungary

THE SYNTHESIS OF THE CORRECTED human ACTH and its fragments offered an excellent possibility to extend the applicability of pentafluorophenylesters (OPfp).[1] As is known, Swiss[2] and Hungarian[3] researchers have found that both in porcine and human ACTH Asn is present instead of Asp in the position 25 and in human ACTH the correct sequence is Gly-Ala in the position 26-27 instead of Ala-Gly. This fact has again raised the well-known problems in the synthesis of Asn-peptides, such as the formation of beta-cyanoalanin and succinimido-derivatives as by-products.[4] In fact, preparing Z-Asn-OPfp by the usual way, a reaction mixture was formed from which the desired product could not be isolated. However, working at 0°C and with short reaction time, Z-Asn-OPfp was obtained with 93% yield; moreover it was possible to recrystallize it from hot ethyl acetate obtaining fine needles with a melting point of 150°C. In a DMF solution this compound completely converts into the corresponding succinimido-derivative within 12-15 hr, Figure 1, confirming the easy formation of the cyclic derivative of the Asn moiety.

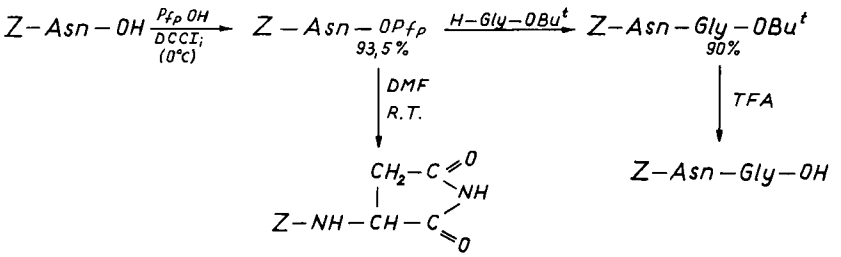

Figure 1: Preparation, use for synthesis and decomposition (Z-aminosuccinimide formation) of benzyloxycarbonyl-asparagine pentafluorophenyl ester.

Z-Asn-Gly-OH was obtained by reaction of this compound and H-Gly-OBu^t followed by TFA treatment. It is worth mentioning, that no example can be found in the literature for acylation with this dipeptide. We used it in the acylation reactions shown in Figure 2.

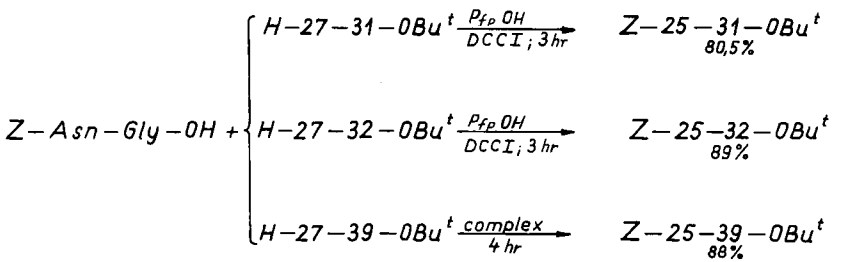

Figure 2: Use of Z-Asn-Gly-OH for fragment condensations.

Equimolar amounts of starting materials were used and the yields ranged from 80% to 90%. The active ester formation took place in a few minutes, as indicated by tlc, and the coupling reactions required a couple of hours. We prefer the use of the DCCI-pentafluorophenol complex because of its easy recrystallisation. During these coupling reactions we never used any excess of base which was sometimes

necessary in the case of pentachlorophenyl esters. This fact led us to the determination of the p_K values of the two phenols which were reported in the literature to be the same.[3,5] We have found that in DMF solution the p_K value of pentachlorophenol (PcpOH) is 5,05 and that of pentafluorophenol (PfpOH) is 6,35. In other words, the latter is present in a less dissociated state. Therefore, protonation of the amino component and concomitant slow down of reaction are less likely to occur.

A further advantage is the easy removal of free PfpOH from the reaction mixture which does not always succeed with PcpOH and particularly with its salts. If a small amount of PcpOH is present at a catalytic hydrogenation after a coupling reaction the HCl formed might cleave acid sensitive protecting groups.

In the synthesis of longer peptides usually elevated temperatures and/or an excess of acylating components are applied to obtain higher yields and purer products.[5] In Figure 3 condensations of larger ACTH fragments are shown. In these steps of the synthesis equimolar amounts of starting components were treated with only a slight excess of DCCI-PfpOH complex at room temperature for 24 hr.

$$Z\text{-}15\text{-}24\text{-}OH + \left\{\begin{array}{l} H\text{-}25\text{-}31\text{-}OBu^t \xrightarrow[5\,hr]{complex} Z\text{-}15\text{-}31\text{-}OBu^t \xrightarrow{Pd/H_2} H\text{-}15\text{-}31\text{-}OBu^t \\ H\text{-}25\text{-}32\text{-}OBu^t \xrightarrow[6\,hr]{complex} Z\text{-}15\text{-}32\text{-}OBu^t \xrightarrow{Pd/H_2} H\text{-}15\text{-}32\text{-}OBu^t \\ H\text{-}25\text{-}39\text{-}OBu^t \xrightarrow[24\,hr]{complex} Z\text{-}15\text{-}39\text{-}OBu^t \xrightarrow{Pd/H_2} H\text{-}15\text{-}39\text{-}OBu^t \end{array}\right\} \longrightarrow$$

$$\xrightarrow[R.T.\ 24\,hr]{Boc\text{-}1\text{-}14\text{-}OH} \left\{\begin{array}{l} Boc\text{-}1\text{-}31\text{-}OBu^t \\ Boc\text{-}1\text{-}32\text{-}OBu^t \\ Boc\text{-}1\text{-}39\text{-}OBu^t \end{array}\right\} \xrightarrow{TFA} \begin{array}{l} H\text{-}1\text{-}31\text{-}OH \\ H\text{-}1\text{-}32\text{-}OH \\ H\text{-}1\text{-}39\text{-}OH \end{array}$$

Figure 3: Fragment condensation scheme in syntheses of corrected human ACTH and of lower homologs by the pentafluorophenol technique.

The protected peptides thus obtained, were treated in the usual way with TFA followed by purification on CM-cellulose columns. The free, chromatographically homogenous peptides showed full biological activity.

An alternative route for the synthesis of the 15-24 sequence is demonstrated in Figure 4. This route has the advantage that it avoids to expose the whole C-terminal

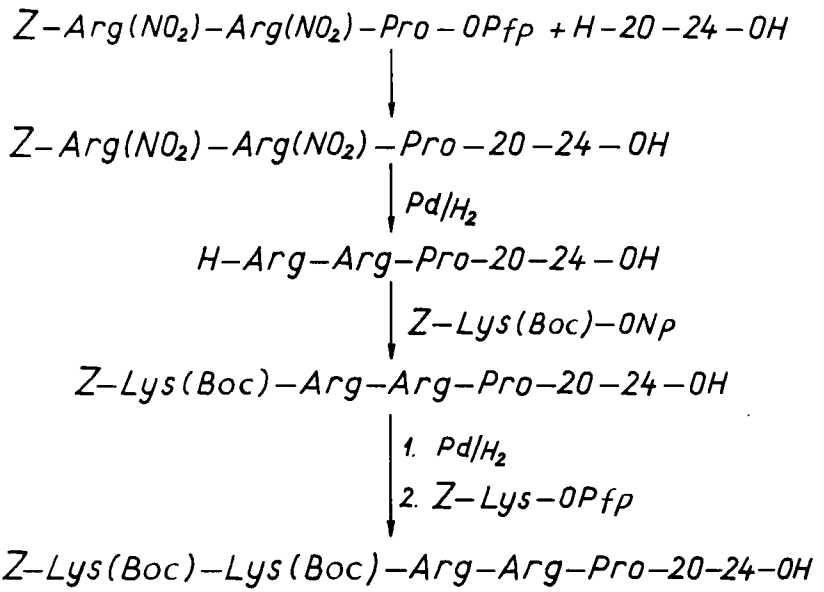

Figure 4: Alternative pathway for synthesis of ACTH-(15-24)-decapeptide.

part, containing many acid sensitive protecting groups, to the time consuming catalytic hydrogenation in acetic acid solution which is needed for the removal of arginine nitro groups. This synthetic pathway presents an example for the acylation of a C-unprotected free peptide by a pentafluorophenyl ester without using a base. In these steps we used first Z-Lys(Boc)-ONp instead of the pentafluorophenyl ester to avoid the formation of an acetyl-derivative which is a real danger in the case of highly activated esters.[6]

In summary, syntheses of corrected human ACTH and its species specific fragments (1-31) and (1-32) were performed without protecting the carboxamide function of asparagine. The pentafluorophenol technique was used in every important coupling step.

CHEMISTRY AND BIOLOGY OF PEPTIDES

SYNTHESIS OF THE HYPOTHALAMIC LH- AND FSH-RELEASING DECAPEPTIDE

G. Flouret, W. Arnold, W. Cole, R. Morgan, W. White, M. Hedlund, R. Rippel.* Division of Antibiotics and Natural Products, Abbott Laboratories, North Chicago, Illinois 60064

THE STRUCTURE OF THE hypothalamic luteinizing hormone-releasing hormone/follicle-stimulating hormone-releasing hormone (LH-RH/FSH-RH) has been described as that of the decapeptide[1] <Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2 (I), for the porcine species.

In order to provide independent confirmation of the validity of structure I for the hormone,[2] we synthesized this decapeptide and attained as well a second goal of providing a convenient route to substantial amounts of decapeptide for the more extensive studies which are required to ascertain its biological role.

In one approach solution methods were employed. Thus, glycinamide was coupled with Z-Pro-ONp to give the dipeptide Z-Pro-Gly-NH_2 (II). Deprotection of II with HBr-AcOH[3] and coupling with Z-Arg(NO_2) and DCC[4] yielded Z-Arg(NO_2)-Pro-Gly-NH_2 (III). Deprotection of III with HBr-AcOH and coupling with Boc-Leu-ONp afforded Boc-Leu-Arg(NO_2)-Pro-Gly-NH_2 (IV). Successive removal of the Boc groups with trifluoroacetic acid (TFA)-CH_2Cl_2 (1:1)[5] and coupling with appropriate Boc-amino acid active esters led to Boc-Trp-Ser(Bzl)-Tyr(Bzl)-Gly-Leu-Arg(NO_2)-Pro-Gly-(NH_2) (VIII). The Boc group of VIII was selectively removed with TFA-CH_2Cl_2 (1:1) containing 1% mercaptoethanol and the triprotected amino-octapeptide amide was coupled with Boc-His by means of DCC to yield Boc-His-Trp-Ser(Bzl)-Tyr(Bzl)-Gly-Leu-Arg(NO_2)-Pro-Gly-NH_2 (IX). After the

*Present Address: Northwestern University, The Medical School, Department of Physiology, 303 East Chicago Avenue, Chicago, Illinois 60611

removal of the Boc group of IX, the triprotected amino-nonapeptide amide was coupled with pentachlorophenyl pyroglutamate[6] to yield the desired triprotected decapeptide <Glu-His-Trp-Ser(Bzl)-Tyr(Bzl)-Gly-Leu-Arg(NO_2)-Pro-Gly-NH_2 (X).

All intermediates were purified by column chromatography on silica gel. Most of them were not crystalline, but pure enough for characterization. Where possible, NMR spectra were determined to corroborate the molecular structure. All intermediates had consistent elemental analyses and gave one spot on tlc. The yields at each step were usually high (70-95%), the overall yield of X was (10%), based on the starting glycinamide.

The tri-protected decapeptide (X) was also assembled by the solid-phase method of Merrifield,[7] with Boc-Gly-Resin being the starting material. An aliquot of the peptide-resin was retained as octapeptide-resin (VIIIa), and the remainder of the material was converted to the decapeptide-resin (Xa). The completed Xa was ammonolyzed to give a high yield (80-100%) of peptide material. Chromatography of this product on silica gel with combinations of MeOH-$CHCl_3$ as the eluent led to pure tri-protected decapeptide X in good yield (35-40%). The melting point, NMR spectrum, optical rotation and tlc pattern of this material were identical to those of the material obtained by solution methods. Thus, the solid-phase method appeared to be a convenient method for obtaining X rapidly and in good yield.

Ammonolysis of VIIIa and chromatography led to pure VIII comparable to the octapeptide made by solution methods according to the criteria of mp, optical rotation, NMR spectra and tlc analysis.

A fragment-condensation method was also employed for making VIII. This was accomplished by a condensation involving the C-terminal tetrapeptide IV and Boc-Trp-Ser(Bzl)-Tyr(Bzl)-Gly (XI). Starting with Gly-OMe, XI was assembled by the stepwise active ester method of Bodanszky[8] employing the appropriate Boc-amino acid-ONp. Saponification of the tetrapeptide methyl ester gave XI. Coupling of both XI and IV in the presence of DCC led to VIII comparable to the material made either by the stepwise method or the solid-phase method, according to the criteria of melting point, NMR and tlc analysis.

The removal of the protecting groups from X was accomplished by treatment with HF-anisole.[9] The product was treated with AG 1-X2 (Acetate) and subjected to a two-step Sephadex gel filtration[10] purification. The lyophilized final product was a fluffy powder obtained in 25-30% yield

from X. Elemental analysis data of synthetic LH-RH/FSH-RH were consistent with a diacetate trihydrate. Amino acid analysis[11] gave the expected values. The optical rotation, $[\alpha]_D^{24} = -50.5°$ (*c* 1, 1% AcOH), was similar to that reported by Geiger.[12] Two dimensional thin-layer electrophoresis (0.1*N* pyridine acetate, pH 6.5) and chromatography (*n*-BuOH-AcOH-H_2O, 4:1:1) showed one component.

The decapeptide I was tested biologically by *in vitro* incubation with male rat hemipituitaries. Release of both FSH[13] and LH[14] were measured and compared with the activity of a synthetic standard shown previously at Abbott and in the laboratories of A.V. Schally[15] to be equal to purified natural hormone. The results of the present *in vitro* experiments demonstrate that I has LH and FSH releasing activities which equal those of a synthetic standard.

Acknowledgment

The authors thank Mrs. J. Hood for elemental analyses, Dr. R. Egan for NMR spectra, Dr. O. Walasek for amino acid analyses, and Dr. A. V. Schally for communicating the structure of the decapeptide I.

SYMPOSIUM DISCUSSIONS

Summarized by Johannes Meienhofer

THE LUCID REPORT[1] of Dr. Klaus Hofmann on the latest progress in the synthesis of ribonuclease T_1 stimulated a very lively discussion. Several inquiries were directed at potential formation of side products during fragment condensation. In reply it was pointed out that detection and identification of small amounts of side products, even of those with known nature, becomes increasingly difficult with progressively larger peptides. Moreover, in a project of the magnitude of an enzyme synthesis, the time factor renders it prohibitive to examine all side products in mother liquors or other secondary fractions.

The inherent question of fragment condensation *versus* incremental (stepwise) chain elongation drew several comments. Limited stability of certain side chain functions as in *S*-ethylcarbamylcysteine (RNase T_1)[1] or tyrosine-*O*-sulfate (cholecystokinin-pancreozymin)[2] makes incremental (stepwise) synthesis very impractible and requires the use of fragment condensation. Intermediates can be tested for homogeneity with presently available analytical techniques. On the other hand, incremental chain elongation allows more readily the use of large excesses of acylating component to increase both yields and coupling rates; thus diminishing the occurrence of certain unimolecular side reactions (rearrangements). In this context it was observed that "recoupling," *i.e.* the subsequent addition of more excess acylating component to a reaction mixture, does usually not produce increased yields, for reasons unknown. This reflects the fact that we still know very little about the kinetics of peptide condensations, and the low solubility of larger fragments further complicates the situation.

α→γ Rearrangements, in particular *via* succinimide formation in aspartyl peptide bonds[3] are of concern. The detection of ω-peptides by enzymatic tests would appear to be impaired since it was observed by several discussants that even the α-bonds in Asp-Asp, Asp-Gly, Asp-Thr, and Glu-Glu are not normally digested by leucine amino peptidase or aminopeptidase M. A new aminopeptidase was mentioned (E. Bricas) that seems to cleave α-peptide bonds between aminodicarboxylic acids.

It was inquired whether chromatographic purification in 50% formic acid as a solvent might cause some formylation of free amino end groups. This was not observed especially since the procedure was done at 4°C. Sephadex is considered stable against 50% HCOOH even at room temperature although traces of carbohydrate might be found in the eluate. A discussant recommended a new lipophilized gel, Sephadex LH-60, for peptide purification. An octadeca- and a nonapeptide had been successfully separated from a heptacosapeptide on LH-60.

The protection of tryptophan residues from oxidation during solid-phase synthesis continues to be a problem. The addition of mercaptoethanol[4] or dithiothreitol[5] and the use of HCl in formic acid (pp 269 to 279) for the cleavage of Boc groups suppressed Trp degradation considerably, especially when working under nitrogen. However, side products are still observed (pp 269 to 279), and it was suggested that mercaptoethanol might give rise to some sulfenylhalide formation that could lead to the known thioether formation with tryptophan.[6]

Attention was drawn to the observation that acetic acid is difficult to be completely washed out of the polystyrene resin after the use of HCl-acetic acid and HCl-dioxane was instead recommended.

The question was raised whether C-terminal fragments of the porcine gastric inhibitory polypeptide might possess biological activity. This has not yet been examined, but it was agreed that it would be useful if this large molecule (43 amino acid residues) would have a smaller active core, as *e.g.* ACTH. However, the steroidogenic activities of active fragments of ACTH approached only in isolated adrenal cell preparations the activity of the intact hormone on a molar basis. In the hypophysectomized rat the naturally occurring 1-39 sequence is still the most potent hormone (not considering synthetic preparations containing D-amino acid or other unnatural residues). Thus, the C-terminal part of ACTH seems to have a role, perhaps in the survival of the hormone.

CHEMISTRY AND BIOLOGY OF PEPTIDES

SOME NOVEL AMINE PROTECTING GROUPS

Daniel F. Veber, Stephen F. Brady, Ralph Hirschmann.
Merck Sharp & Dohme Research Laboratories, Division of Merck & Co., Inc., Rahway, New Jersey 07065

IN PUBLICATIONS FROM THESE laboratories dating back to 1966[1] we showed that fewer protecting groups were required than had generally been employed in peptide synthesis. We have concluded that protection is required only for the α-amino groups, the ε-amino group of lysine and the thiol of cysteine. We employed this strategy in the synthesis of S-protein choosing to protect the α-amino groups with Boc, the ε-amino group of lysine with Z and the thiol with Acm.[2] Although the previous literature indicated that this choice of protecting groups would not present problems, we became aware of two deficiencies in our choices for amine protection. The first of these was the partial loss of Boc during isolation procedures when using 50% aqueous acetic acid as solvent. The second was the partial loss of Z during removal of the Boc protecting group. Recently, significant advances have been made in enhancing the specificity of the removal of the Boc protecting group in the presence of Z.[3] Although such studies have been of great value and have been successful in model cases, other factors such as the poor solubility of starting materials or product may cause problems. Furthermore, nucleophilic scavengers are often required to trap cations generated during the removal of protecting groups. Since the removal of the Z group shows considerable SN_2 character while the removal of the Boc group is largely SN_1, the presence of such a scavenger reduces the selectivity. Such effects are exemplified in Table I. The rate of removal of the benzyloxycarbonyl group is significantly enhanced by the

Table I

Half-Times (Min) for Protecting Group Removal

	Formic Acid	Formic Acid-DMS* (4:1)	Formic Acid-CH_2Cl_2 (4:1)
Boc-Phe	4	26	21
	TFA†	TFA-DMS (4:1)	TFA-Benzene (4:1)
Z-Phe	300	60	600

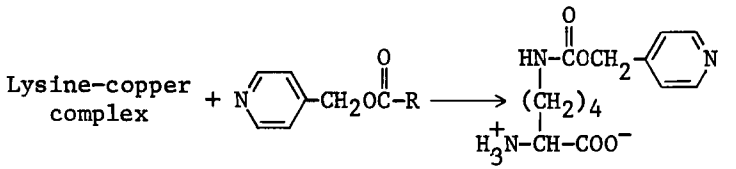
*DMS, Dimethylsulfide.
†TFA, Trifluoracetic acid.

presence of dimethyl sulfide, a good nucleophile, but slowed by the presence of an inert, nonpolar solvent such as benzene. On the other hand the removal of the Boc protecting group which proceeds largely by an SN_1 mechanism is slowed by the presence of dimethyl sulfide as well as by methylene chloride. This is presumably due to the reduced solvent polarity.

We wish to report a solution to the problem of selectivity which involves the use of the novel isonicotinyloxycarbonyl group (iNOC) for the protection of the ε-amino group of lysine. Due to the positive charge on the pyridine ring under acidic conditions, this protecting group is completely stable in liquid HF or TFA and is only slowly removed by HBr/acetic acid. The iNOC protecting group is, however, removed smoothly either from a protein or from a smaller peptide by zinc dust in 50% aqueous acetic acid. Catalytic hydrogenation has also been found useful for the removal of the protecting group from peptides. To show that the chemical reduction can be applied to proteins, 6.5 out of a possible 9-tritium labelled iNOC groups were first introduced into acetamidomethylated, reduced ribonuclease S-protein.[4] Complete removal of the tritium label from the protein was then accomplished by treatment with zinc dust in 50% aqueous acetic acid at room temperature.

Peptides containing ε-iNOC-lysine have been synthesized both by classical and solid-phase techniques. Subsequent removal of the protecting group proceeded smoothly. An additional advantage of the protecting group is in the observation that it confers increased solubility both in aqueous and organic solvents, on peptides. This protecting group should also give advantages in purification by ion

exchange chromatography as observed by Young for the 4-picolyl ester protecting group.[5] ε-Isonicotinyloxycarbonyl-lysine (II) was prepared from lysine-copper complex by reaction with isonicotinyl succinimidoyl carbonate (Ia) or isonicotinyl *p*-nitrophenyl carbonate (Ib).



(I) (II)

a) R, OSu : mp 106-107.5°, ethyl acetate-hexane — mp 234° water-ethanol

b) R, ONp : mp 105-106°, ethyl acetate-hexane

The α-Boc derivative (mp 82-83.5° from isopropanol-hexane) was prepared by treatment of II with *t*-butyl succinimidoyl carbonate and by treatment of α-Boc-lysine with Ia or Ib. Ia and Ib were prepared by treatment of succinimidoyl chloroformate and bis-*p*-nitrophenyl carbonate, respectively, with 4-pyridine carbinol in the presence of N-methylmorpholine.

To find an α-amino blocking group which is stable in 50% acetic acid, we have examined several alkoxycarbonyl derivatives which we hoped might be more stable than Boc in this solvent system and yet be sufficiently labile under acidic conditions to be useful in peptide synthesis. We also wanted the new protecting group to be at least comparable to Boc in its effect on peptide solubility.

In order to predict the rate of removal of various urethane-type protecting groups under acidic conditions we have used the rates of solvolysis of various derivatives (tosylate, chloride and nitrobenzoate) of the corresponding alcohols as a guide. The feasibility of such an approach had been suggested by Bláha and Rudinger.[6] This approach cannot be used to precisely predict the stability of the protecting groups for several reasons. First, rates of solvolysis for a variety of derivatives are reported under varying solvolysis conditions, making direct comparisons impossible. Secondly, the degree of SN_1 character is not constant but is dependent on the nature of the alcohol. Finally, the rate of solvolysis of the tosylate of *t*-butanol,

needed to serve as a reference point for Boc, is not known. A somewhat empirical approach was therefore required.

The following derivatives of phenylalanine were prepared: cyclopropylcarbinyloxycarbonyl, 1-cyclopropylethoxycarbonyl, 1-methylcyclohexyloxycarbonyl and 1-methylcyclobutyloxycarbonyl. Each of these was characterized by physical means and shown to be a single component by tlc. These alkoxycarbonyl-amino acids were prepared from the alcohols via the chloroformate derivatives which were not purified except to remove excess phosgene *in vacuo*. The rate of removal of these groups has been studied in trifluoroacetic acid and formic acid (Table II). It was

Table II

Half-Times (Min) for Amine Protecting Group Removal

1-cyclopropylethoxycarbonyl	-	1.5	-	-

*Complete in 1 min.
†Complete in 1-2 min.

found that the 1-methylcyclobutyloxycarbonyl (McBoc) group had essentially the desired stability properties. It could be removed completely with trifluoroacetic acid in less than 30 min at 20°, yet it was stable in 50% acetic acid for 48 hours. A sample of Boc-Phe stored in 50% acetic acid showed about 10-15% loss of the protecting group in 48 hours. The 1-methylcyclobutyloxycarbonyl group should find use primarily for the protection of the amino terminus of a relatively large peptide which is to be purified without loss of protection in an acidic solvent system such as 50% acetic acid. Some of the other protecting groups may

also prove of value when special lability or stability relative to the Boc group is required. It should be pointed out that for a given protecting group the rate of acid catalyzed cleavage from an amino acid is about twice that of a peptide due to the reduced basicity of the urethane function in a protected peptide.

The use of these two novel protecting groups, iNOC and McBoc, in conjunction with Boc and Acm fill the requirements for the protection of the three functionalities which require protection. In addition to the favorable properties of each of these protecting groups individually, the removal of iNOC, Acm and Boc/McBoc is based on "chemical" selectivity rather than kinetic differences in the rate of removal. We conclude that tactics based on such chemical selectivity should reduce side reactions in the synthesis and purification of large peptides and thus introduce a greater degree of certainty.

CHEMISTRY AND BIOLOGY OF PEPTIDES

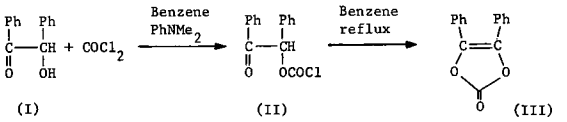
THE 4,5-DIPHENYL-4-OXAZOLIN-2-ONE GROUP AS A PROTECTING GROUP IN PEPTIDE SYNTHESIS

Frank S. Guziec, Jr., John C. Sheehan. Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts

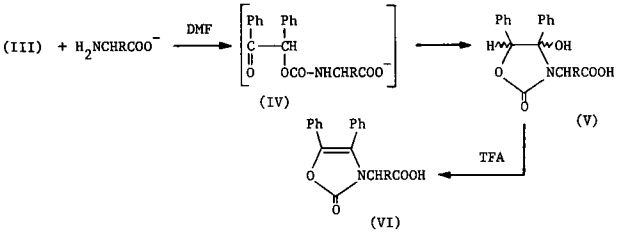
OCCASIONALLY IN PEPTIDE SYNTHESIS it would be advantageous to block a nitrogen function by replacing both hydrogens of a primary amine. Previous protecting groups of this type include the phthalimido,[1] 2-hydroxyarylidine,[2] and others[3-6] which have not attained widespread use due to solvolytic instability. We have succeeded in incorporating the amine nitrogen of primary amino acids into the extremely stable and unreactive 4,5-diphenyl-4-oxazolin-2-one ring system[7] while devising convenient methods for the removal of this protecting group.

Treatment of a mixture of benzoin (I) and phosgene in benzene with *N*,*N*-dimethylaniline, followed by cyclization of the unstable chloroformate (II) in refluxing benzene gives the unsaturated carbonate (III) in 65-70% yield (Equation 1). The carbonate is a crystalline compound which may be stored at room temperature for long periods without decomposition.

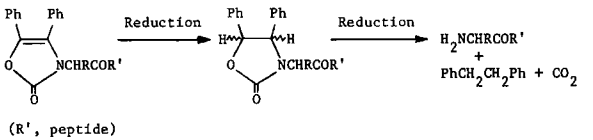
Treatment of a suspension of an amino acid tetramethylammonium salt in dimethylformamide (DMF) with the carbonate (Equation 2) gives an intermediate urethane (IV) which cyclizes under reaction conditions to the diastereomeric mixture of hydroxyoxazolidinones (V). The mixture may be clearly and quantitatively dehydrated to the desired 4,5-diphenyl-4-oxazolin-2-one derivative (VI), for which we propose the abbreviation "Ox," in overall yields of 75-85%. The "Ox" compounds are generally highly crystalline solids which fluoresce under ultraviolet light ($\lambda_{max} \sim 400$ mμ).



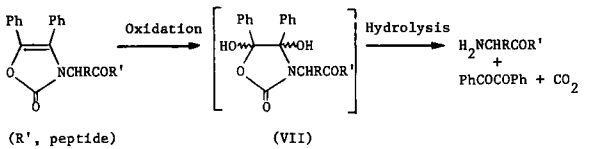
Equation 1



Equation 2



Equation 3



Equation 4

Compounds of the general structure (VI) are stable to a variety of rigorous conditions: aqueous alkali, refluxing ethanolic hydrazine, ethanolic hydrogen chloride, hydrogen bromide in acetic acid, refluxing trifluoroacetic acid (TFA), and anhydrous hydrogen fluoride.

The 4,5-diphenyl-4-oxazolin-2-ones may be considered "protected" *N*-carbobenzoxy-*N*-benzyl derivatives. Thus, the "Ox" protecting group may be removed by a series of reductions (Equation 3). Low pressure (Parr) hydrogenation over palladium on charcoal in solvents containing an equivalent of aqueous acid most conveniently frees the amine function in nearly quantitative isolated yield.

Similarly the group may be removed by reduction with sodium in liquid ammonia.

Alternatively the vinyl oxygen, vinyl nitrogen moieties of the "Ox" group may be considered potential carbonyl functions. Oxidation to a dihydroxy compound (VII) followed by mild hydrolysis would free the amine (Equation 4). Oxidation of "Ox" derivatives in trifluoroacetic acid with excess *m*-chloroperbenzoic acid, followed by a hydrolytic workup frees the amine in 70% yield.

Simple "Ox" dipeptide derivatives have been prepared without difficulty using the water soluble 1-ethyl-3-(3-dimethylamino)propyl carbodiimide hydrochloride, and pure dipeptides isolated in high yield upon deprotection and hydrolysis.* No racemization has been observed in the preparation of "Ox" derivatives, stability studies, coupling or deprotection reactions. Investigations continue concerning the applicability of "Ox" protection in more complex peptides, especially in protection of the ε-amino group of lysine.

AMIDE PROTECTION IN CLASSICAL PEPTIDE SYNTHESIS

S. Bajusz, A. Turán, I. Fauszt. Research Institute for Pharmaceutical Chemistry, Budapest, Hungary

APART FROM WELL KNOWN side known side reactions as trans-peptidation or deamidation, the classical synthesis of free amide group-containing peptides may involve difficulties owing to hydrophilic intermediates which are hard to purify. Peptide derivatives wherein more than one glycine, proline or another amino acid with a hydrophilic side chain like arginine, histidine, serine, or threonine reside in the immediate vicinity of the amide groups of asparagine, glutamine or terminal amide are particularly hydrophilic.

It was found that extreme hydrophilicity of such intermediates could be eliminated by linking a hydrophobic substituent to the free amide group, *i.e.* by amide protection. As a consequence, the peptide derivatives obtained could be easily purified by simple procedures.

This second function of amide blocking may be demonstrated by the synthesis of intermediate products of salmon calcitonin listed in Table I as in this case no side reactions were observed even in preparations without amide blocking. These peptide derivatives and their intermediates were purified merely by extractions with aqueous solutions or by crystallization. All syntheses with amide protection using Geiger's 4.4'-dimethoxy-benzhydryl group (Mbh)[1] proved to be more efficient than those without it.[2] The only exception was the preparation of tetrapeptide sequence Cys-Ser-Asn-Leu wherein, however, one serine residue is found. The expression of efficiency, E_f, was based on the utilization of amino acid derivatives applied in the coupling reactions instead of amino acids proposed by Rydon:[3]

$$E_f = \frac{n \cdot m_{pp} \cdot 100}{m_{Ad}}$$

Table I

Efficiencies E_f of Syntheses of Protected Peptides Containing Blocked or Free Amide Groups

#Yield of saponification.

where n is the number of amino acid residues in the peptide chain, m_{pp} is the number of moles of pure peptide obtained and m_{Ad} is the total number of moles of amino acid derivatives used in the coupling reactions.

The intermediates (listed in Table II) containing only one neighbouring serine or threonine or protected hydrophilic side chains, *e.g.* Glu(OBu^t), Lys(Boc), were prepared without any isolation or purification problems.

The synthesis[4] of TRH as shown in Figure 1 may be another example. Amide protection in the synthesis of this tripeptide, <Glu-His-Pro-NH_2, afforded directly a pure, homogeneous end-product, without using any chromatographic procedure for the purification of intermediates, *i.e.* H-His-Pro-NH-Mbh, Z-<Glu-His-Pro-NH-Mbh, or TRH itself. The efficiency of the synthesis was 52% being equal with that of the best performed classical synthesis of TRH published by Flouret,[5] wherein column chromatography was used for purifying an intermediate and the end-product.

Table II

2. Z-Lys(Boc)-Leu-Ser-Gln-Glu(OBu^t)-Leu-$NHNH_2$	38
3. Z-His(Z)-Lys(Boc)-Leu-Gln-Thr-Tyr-Pro-OH	26

In the synthesis of peptide amides containing acid-sensitive residue(s), however, amide blocking is not an advantageous tool because acidolysis is the only process for removing any of the known amide masking groups. In such cases difficulties, mentioned above, can also be overcome by blocking the hydrophilic third function in the neighbourhood of amide bearing residues. Occasionally salt formation of peptide amides with some hydrophobic acid, like pentachlorophenol, can also be effective. A third possibility to facilitate purification or isolation of intermediate products in the synthesis of peptides amides

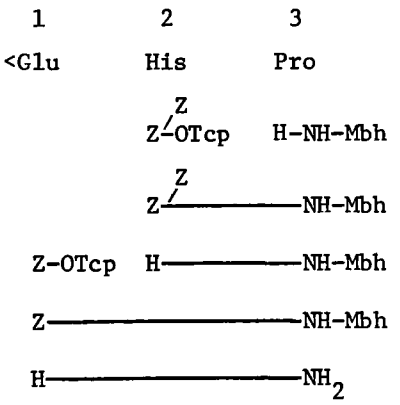

Figure 1: Synthesis of thyrotropin releasing hormone (TRH) using amide protection.

may be condensation of free amide group-containing amino acids with longer hydrophobic fragments. The considerations discussed above can, of course, not be generalized. Nevertheless, they have proved to be good for the synthesis of luteinizing hormone-releasing hormone (LH-RH).

As shown in Figure 2, the sequence of the decapeptide amide, <Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2, was built up by the condensation of glycine-peptide 1-6 and tetrapeptide component 7-10 to avoid the risk of racemization.

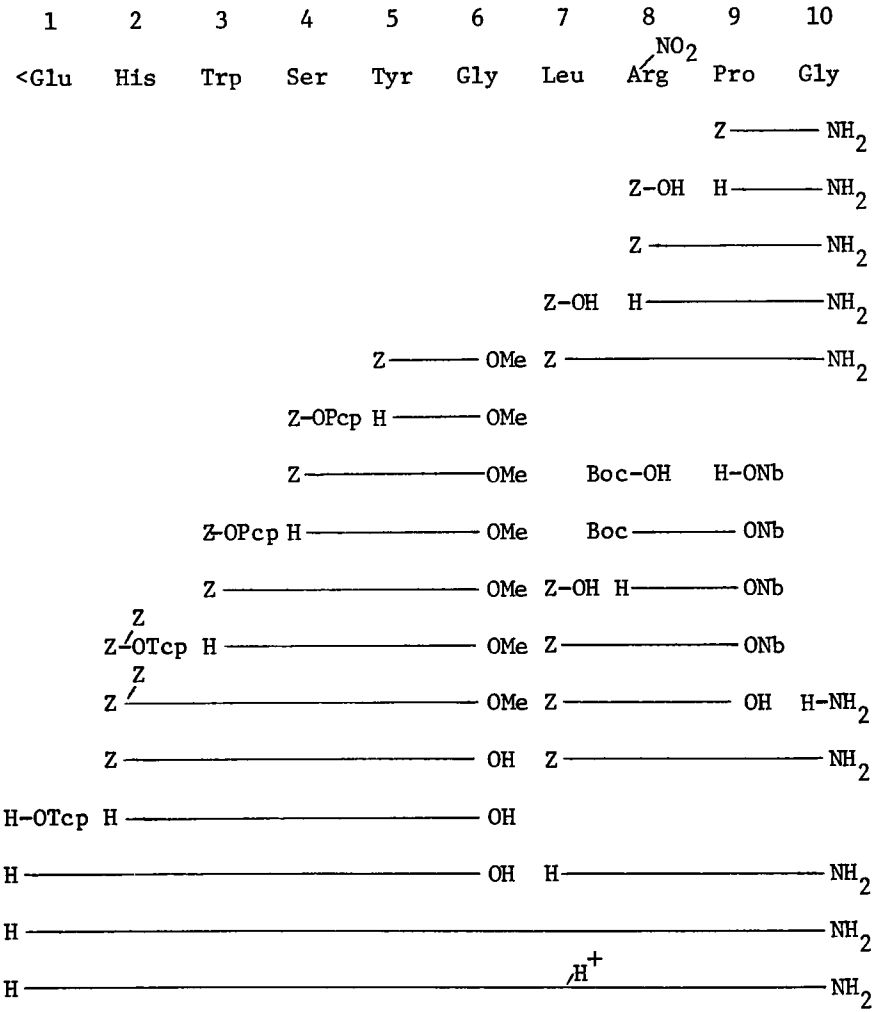

Figure 2: Synthesis of luteinizing hormone-releasing hormone (LH-RH) with and without use of amide protection

The synthesis of peptide 1-6 was accomplished in a stepwise manner starting from glycine methyl ester and using chlorophenyl esters for acylation. The C-terminal methyl ester group was saponified at the pentapeptide stage and the free pentapeptide was coupled with either carbobenzoxy-glutamine, carbobenzoxy-pyroglutamic acid or pyroglutamic acid via activated esters. The latter gave the best result and the hexapeptide could be obtained in a yield over 90%.

In the synthesis of the tetrapeptide component, both the free guanidino group containing intermediates and carbobenzoxy-nitro-arginyl-prolyl-glycine amide are hydrophilic. It is of interest, however, that the pentachlorophenol salts of prolyl-glycine amide and of leucyl-nitro-arginyl-prolyl-glycine amide could be crystallized from water. Therefore the second version of the synthesis of protected tetrapeptide was chosen coupling glycine amide to the partially protected tripeptide 7-9. Coupling of the two components was accomplished by the dicyclohexylcarbodiimide-pentachlorophenol method.

Purification by chromatography could be omitted again. The hexapeptide 1-6, the nitro-decapeptide amide and LH-RH were purified by precipitation from aqueous solution with acetone. The synthesis presented here was rather efficient as the pure LH-RH was obtained in a yield of 30% based on the amino acid derivatives used in the coupling reactions.

CHEMISTRY AND BIOLOGY OF PEPTIDES

THE PREPARATION AND USE OF CARBOXAMIDE PROTECTED ASPARAGINE AND GLUTAMINE DERIVATIVES

Victor J. Hruby, F. A. Muscio, W. Brown, Peter M. Gitu.
Department of Chemistry, University of Arizona, Tucson, Arizona 85721

THE PRESENCE OF ASPARAGINE or glutamine in peptides can provide several undesirable side reactions in the course of synthesis including dehydration to nitrile, pyroglutaminyl formation, hydrolysis, and imide formation. The rather labile bis(2,4-dimethoxybenzyl),[1,2] and 2,4-dimethoxybenzyl groups[3] have been suggested as possible carboxamide protecting groups to eliminate some of these side reactions.

We have been examining the potential of the diphenylmethyl, 2,4-dimethylbenzyl, 3,4-dimethoxybenzyl, 4-methoxybenzyl, 2,3-dimethoxybenzyl, 2-methoxybenzyl, 4-methylbenzyl, and benzyl groups as carboxamide protecting groups. The mono acetamide derivatives of each of these groups (*e.g. N-N*-diphenylmethylacetamide, *N*-2,4-dimethylbenzylacetamide, *etc.*) were prepared. All of these compounds are stable in trifluoroacetic acid (TFA) at room temperature. The rates of solvolysis of these amides were studied at 51° in TFA, and the relative labilities of these protecting groups were studied in 2.5 *N* HBr-HOAc and liquid HF at room temperature. The ease of solvolysis of these groups follow the order: diphenylmethyl > 2,4-dimethylbenzyl $\gtrsim$ 4-methoxybenzyl $\gtrsim$ 3,4-dimethoxybenzyl $\gtrsim$ 2,3-dimethoxybenzyl > 2-methoxybenzyl >> 4-methylbenzyl > benzyl. The product of the reaction was acetamide--no acetic acid was detected.

Asparagine and glutamine derivatives possessing the diphenylmethyl, 2,4-dimethylbenzyl, the 3,4-dimethoxybenzyl, and the 4-methoxybenzyl carboxamide protecting groups were synthesized. The results of a quantitative study of the

solvolysis of these derivatives in liquid HF for 75 min at 20° using amino acid analysis is given in Table I. When the protecting groups were removed only asparagine and glutamine were obtained--no aspartic acid or glutamic acid was detected.

Table I

HF Cleavage of Asparagine and Glutamine Carboxamide Protecting Groups

Compound	*% Protecting Group Removed*
Boc-Asn(diphenylmethyl)-OBzl	100
Boc-Gln(diphenylmethyl)-OBzl	100
Boc-Asn(2,4-dimethylbenzyl)-OBzl	100
Boc-Gln(2,4-dimethylbenzyl)-OBzl	25
Boc-Asn(4-methoxybenzyl)-OBzl	>90
Boc-Gln(4-methoxybenzyl)-OBzl	30
Boc-Asn(3,4-dimethoxybenzyl)-OBzl	100
Boc-Gln(3,4-dimethoxybenzyl)-OBzl	10

The diphenylmethyl group was used for asparagine carboxamide protection in the synthesis of [2-phenylalanine, 4-leucine]-oxytocin by the solid phase method using a benzhydrylamine resin. The Boc-asparagine(diphenylmethyl) was coupled quantitatively to the growing peptide chain by dicyclohexylcarbodiimide. The oxytocin derivative was obtained in high yield from the protected resin peptide by treatment with liquid HF followed by oxidation and purification. Other peptides are being synthesized using various amide protecting groups.

CHEMISTRY AND BIOLOGY OF PEPTIDES

THE SYNTHESIS OF THE POLYMERIC A-CHAIN DISULFIDE OF SHEEP INSULIN

Waleed Ohan Danho. Medical Research Center, University of Baghdad, Baghdad, Iraq

Ernie Engels. Deutsches Wollforschungsinstitut an der Technischen Hochschule Aachen, Aachen, Germany

THE PROBLEMS OF PROTECTING sulfhydryl(-SH) function in cystein containing peptides and proteins are well-known. An ideal sulfhydryl protecting group, which resists all intermediate steps of peptide synthesis and which can be easily removed at the final step is still to be found.[1]

Zahn and co-workers[2] described the synthesis of the polymeric B-chain of insulin by using a new tactic in order to overcome the problems of sulfhydryl protection. They renounced the usual sulfhydryl protection by synthesizing symmetrical cystine peptides and converted them into cysteine peptides in the final stage of the synthesis. This principle of using cystine peptides instead of S-protected cysteine peptides was hardly popular and previously was used only for preparing shorter peptide fragments.[3]

In the case of larger cystine peptides, decomposition of disulfide bonds was believed to occur. In addition, cystine peptides having twice the molecular weight of cysteine peptides should become quite insoluble.

The large cystine peptides, with the amino acid sequences in the B-chain of bovine insulin $(B\ 1\text{-}16)_2$ and $(B\ 17\text{-}30)_2$ were readily prepared by using conventional methods of peptide synthesis.[2] No decomposition of cystine sulfur occurred during the main steps of the synthesis. Coupling of these large cystine peptides yielded the

polymeric B-chain which was easily converted to 7,19-*S*-sulfonate via oxidative sulfitolysis. The insulin forming potency of this preparation was higher than that of a previously published *S*-benzyl-cysteine protected B-chain.

This success encouraged us to use this principle for a new synthesis of the A-chain of sheep insulin. However, it was rather difficult to use this tactic for the whole of the A-chain of insulin. Since the A-chain contains four cysteine residues, one has to synthesize four cystine peptides (Figure 1 C). However, if any two of them would

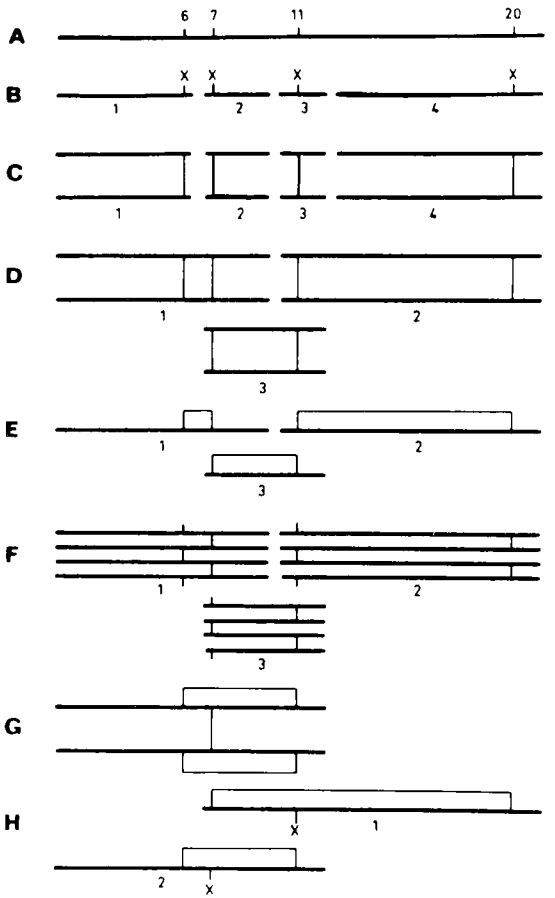

Figure 1: Schematic representation of possible disulfide-containing intermediates for insulin A-chain synthesis.

be coupled, polymers (Figure 1 F) would already be obtained at this intermediate stage, instead of the desired cystine peptides shown in Figure 1 D. Coupling of intermediate polymers (Figure 1 F) to form polymeric A-chain would appear to be extremely difficult. A possible approach is the coupling of cystine peptides in monomeric cyclic form (Figure 1 E).

Finally, it should be possible to work with cystine peptides in which some other cysteine residues have been *S*-protected, as in the cyclic cystine peptides shown in Figure 1 H.

Results

The present work describes the synthesis of the polymeric A-chain disulfide of sheep insulin in which two cysteine residues namely A_7 and A_{20} were protected by using cystine and the remaining cysteine residues in A_6 and A_{11} were protected by using the trityl-protecting group,[4] which can be easily removed by HBr-CF_3COOH.[5] Two large cystine peptides with the amino acid sequences of $(A\ 1\text{-}9)_2$ and $(A\ 10\text{-}21)_2$ were prepared by condensing the fragments A 1-4 with $(A\ 5\text{-}9)_2$ and A 10-12, A 13-16 with $(A\ 17\text{-}21)_2$ respectively using conventional methods of peptide synthesis.

The plans for the synthesis of these fragments are outlined in Figure 2 and Figure 3. The protected peptides were characterized by elemental and amino acid analysis, and by thin layer chromatography in several solvent systems. Physical data are shown in Table I. Coupling of the large cystine peptides $(A\ 1\text{-}9)_2$ and $(A\ 10\text{-}21)_2$ by the azide method[6] (Figure 4) should give a mixture of A-chain dimer and A-Chain polymer. The A-chain polymer was the main product (optical rotation - 31.6°, c=1, HPT). The following numbers of the amino acid residues per molecule were found in acid hydrolysate (6 *N* HCl, 48 hours, 110°C): 2.29 Asp, 0.80 Ser, 4.00 Glu, 2.00 Gly, 0.95 Ala, 1.20 Val, 0.20 Ile, 1.97 Leu, 1.36 Tyr.

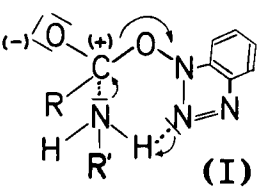
CHEMISTRY AND BIOLOGY OF PEPTIDES

NEW CATALYSTS IN PEPTIDE SYNTHESIS

Wolfgang König, Rolf Geiger. Farbwerke Hoechst AG, D-623 Frankfurt-Höchst, Germany

WE REPORTED PREVIOUSLY[1,2] on the 1-hydroxybenzotriazole ester (OBt) and on the possibility of decreasing racemization by the addition of 1-hydroxybenzotriazole (HOBt) to dicyclohexylcarbodiimide-mediated peptide condensations. To compare the reactivity of these new esters with that of other active esters, we synthesized Z-Phe-Val-*o*-nitranilide and determined reaction rates spectrophotometrically. Figure 1 shows a comparison of reactivities of the 2,4,5-trichlorophenyl ester (OTcp), the *N*-hydroxysuccinimide ester (ONSu), and the OBt ester in dimethylformamide (DMF) and tetrahydrofuran (THF). It is known that *p*-nitrophenyl esters react faster in DMF than in nonpolar solvents.[3] The OTcp esters behave analogously, Figure 1. Kemp suggested[4] that the ONSu esters react more slowly in DMF than in THF, a fact which we could not confirm in this test. However, the reactivity of the OBt ester is much faster than that of the other active esters. Probably a complex (I) is formed between the amine and the OBt ester which, due to the strong polarization of the carbonyl group, reacts rapidly to give the amide.



(I)

Recently we discovered a new property of HOBt. It catalyzes the aminolysis of *p*-nitrophenyl or trichlorophenyl esters, particularly in DMF or dimethylacetamide solution. The moderate catalysis of thiophenyl and *p*-nitrophenyl esters by imidazole is well known.[5,6] More active are the "bifunctional catalysts,"

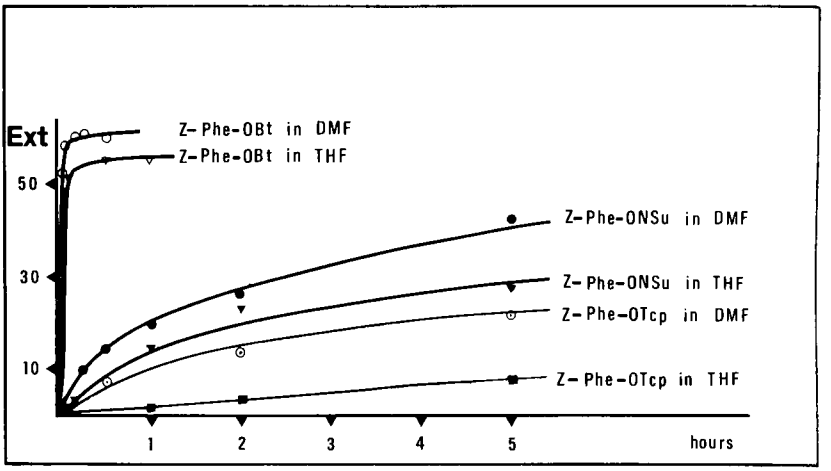


Figure 1: Active ester synthesis of Z-Phe-Val-*o*-nitranilide, monitored spectrophotometrically at 350 nm in ethyl acetate [*c* valine-*o*-nitranilide, $5.10^{-3}M$; *c* Z-Phe-active ester, $1.10^{-2}M$]. Samples were extracted with $NaHCO_3$ and 2 *N* HCl prior to reading. (OBt ester samples were treated with NaOH prior to extraction.)

e.g. certain pyrazole derivatives, 2-hydroxypyridine and 1,2,4-triazole.[7,8] However, these catalysts are effective in nonpolar solvents only and not in DMF.[3] The strong catalytic effect of HOBt on the aminolysis of Z-Phe-OTcp in DMF can be seen in Figure 2. In THF, however, HOBt inhibits the aminolysis of the trichlorophenyl ester. Figure 3 shows that the aminolysis of *N*-hydroxysuccinimide esters can also be catalyzed by HOBt in DMF, although not as effectively as that of the 2,4,5-trichlorophenyl esters.

As the reaction curves of the OBt esters and those of the HOBt-catalyzed OTcp esters are virtually identical, the question arises as to whether OBt esters are formed as intermediates. This appears to be unlikely since Z-Phe-OBt and *p*-nitrophenol actually form Z-Phe-ONp in DMF solution.

A systematic investigation of the catalytic properties of other *N*-hydroxy compounds revealed that those with an acidity similar to acetic acid are suitable as catalysts. For rapid appraisal of catalytic potency we measured the effects of the additives on the half-time of the following reaction: Z-Val-ONp + cyclohexylamine → Z-Val-cyclohexylamide + *p*-nitrophenol. The absorbance of the liberated *p*-nitrophenol

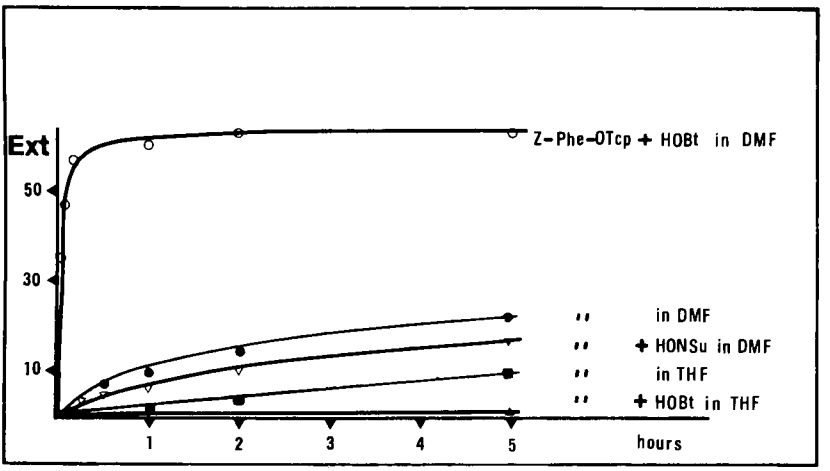

Figure 2: Reaction of Z-Phe-OTcp with H-Val-*o*-nitranilide (yield determined by UV ext at 350 nm).

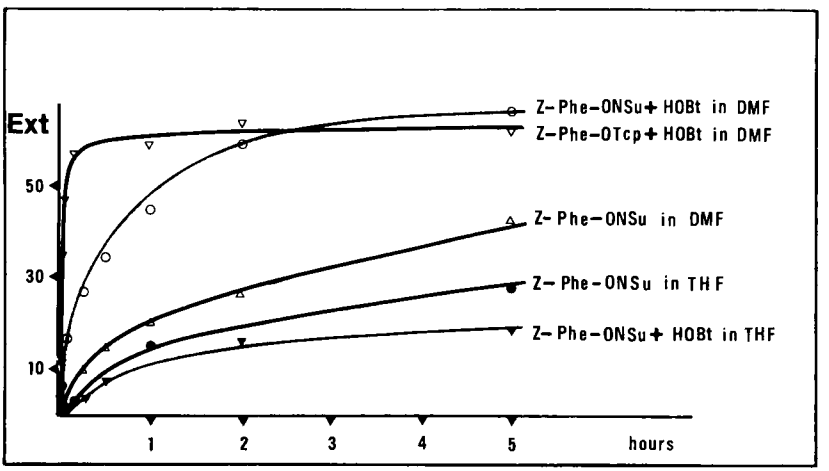

Figure 3: Reaction of activated esters of Z-Phe with H-Val-*o*-nitranilide (yield determined by UV ext at 350 nm).

was determined at 330-300 nm at regular time intervals. Only those *N*-hydroxy compounds which possess approximately the pK of acetic acid have a catalytic effect (Table I). More basic compounds as 1-hydroxypiperidine do not effect catalysis. If the additives are more acidic than HOAc *e.g.* 1-hydroxybenzotriazoles with a substituent having a minus-I-effect, the catalytic activity becomes progressively weaker.

Catalysis of various weakly activated esters by HOBt was examined by means of the Z-Phe-Val-OMe model synthesis. The disappearance of H-Val-OMe was observed by tlc. 1-Hydroxypiperidine esters, cyanomethyl esters, phenyl esters and *p*-chlorophenyl esters could not be catalyzed. 2,4-Dichlorophenyl, 2-chloro-4-nitrophenyl and pentachlorophenyl esters were catalyzed, though not to the same degree as the 2,4,5-trichlorophenyl and *p*-nitrophenyl esters.

The effectiveness of these new catalysts in cases of extreme steric hindrance was tested in the synthesis of Nps-Ile-Cys(Trt)-Ser-Leu-OH, a tetrapeptide of the A-chain of human insulin. Excess active ester of Nps-Ile is reacted in DMF with H-Cys(Trt)-Ser-Leu-OH. The disappearance of the tripeptide is examined by tlc. As can be seen from Table II, the reaction is not completed within a foreseeable period of time both with the OTcp and the ONSu ester. While the reaction rate of the ONSu ester is not accelerated with 3-hydroxy-4-oxo-3,4-dihydro-quinazoline, that of the OTcp ester is more or less catalyzed depending on the added compound. The reactivity of the 2-chloro-4-nitrophenyl ester is catalytically enhanced while aminolysis of the 2,4-dinitrophenyl ester is inhibited by the same compound. According to this test the following are particularly suitable catalysts: 1-hydroxybenzotriazole, 3-hydroxy-4-oxo-3,4-dihydro-quinazoline and 1-hydroxy-2-pyridone. However, 1-hydroxybenzotriazole should not be used with Nps-amino acids or peptides, as the Nps group is partly split off, as was first observed by J. Rudinger (personal communication).

The basicity of the amine plays also an important part. We failed completely in our attempt to prepare nitranilides in this way. The catalysis described is apparently dependent on four prerequisites: only a correct combination of solvent, activated ester, *N*-hydroxy compound and amine results in a successful, rapid peptide synthesis. The powerful catalytic effect on 2,4,5-trichlorophenyl esters and *p*-nitrophenyl esters in DMF on the one hand, and the inhibition of these esters in THF on the other, and furthermore, the inhibition of more highly activated esters in DMF, suggest that the *N*-hydroxy compounds might form two

CHEMISTRY AND BIOLOGY OF PEPTIDES

ON THE REPETITIVE EXCESS MIXED ANHYDRIDE METHOD FOR THE SEQUENTIAL SYNTHESIS OF PEPTIDES. SYNTHESIS OF THE SEQUENCE 1-10 OF HUMAN GROWTH HORMONE

H. C. Beyerman. Laboratory of Organic Chemistry, Technische Hogeschool, Julianalaan 136, Delft, The Netherlands

GIVING HISTORICAL INTRODUCTIONS at this meeting was discouraged, but I feel that I ought to give a short introduction because the work that we have done isn't completely new. It's just another step forward, we think, of what has been done by other people.

The method which we call REMA-method, *r*epetitive *e*xcess *m*ixed *a*nhydride method, as you know, is based on work done in 1951 when three groups, headed by Boissonnas,[1] Wieland,[2] and Vaughan,[3] started to use mixed anhydrides of the carbonates (Table I). However, these were found to give considerable racemization, and it was only after Anderson[4] in the United States and Wieland[5] in Germany found conditions for racemization-free coupling that these anhydrides could be used with more advantage. The late Friedrich Weygand in Germany then used an excess of symmetrical anhydrides[6,7] in order to force reactions to completion. This principle of excess has been used with success by other people, notably by Bodanszky, *et al.*[11] with active esters. However, symmetrical anhydrides are difficult to prepare, and it was Weygand's pupil Tilak[8,9] who in the United States, when using excess mixed anhydrides, found that the relative small excess could be destroyed by potassium hydrogen carbonate. The yields with small peptides were so high that the method could be applied without purification of the intermediate products, that is, in a repetitive way.

Table I

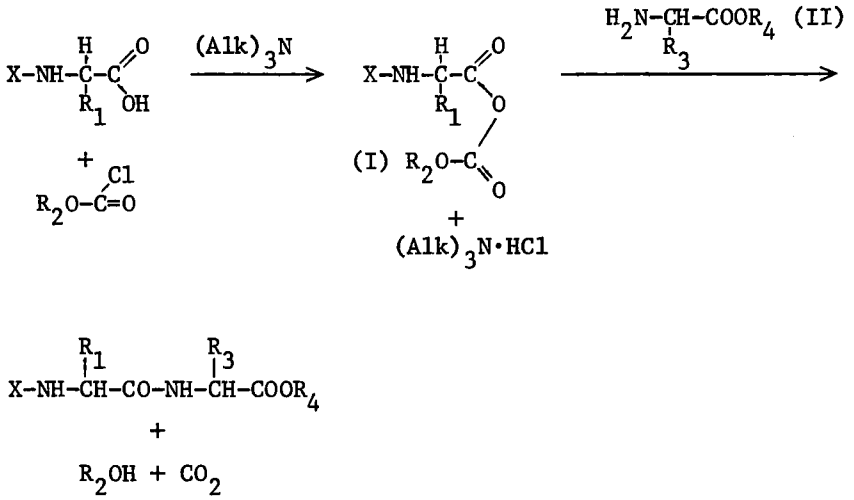
1972	Tilak, *et al.*[9]	
1972	Floor, deLeer, Beyerman[10]	Human Growth Hormone 1-10 (also *fragment* coupling)

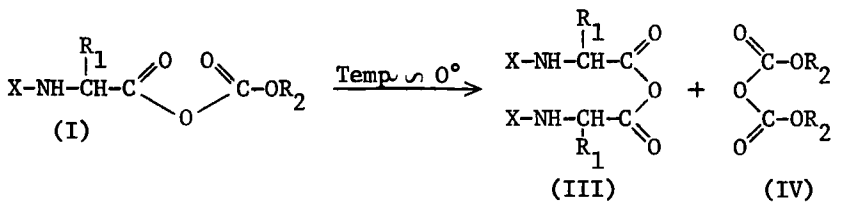
I would like to report here, as an example of a larger peptide, the REMA-synthesis of a sequence of human growth hormone, HGH 1-10. We used with success fragment coupling in order to circumvent a very disagreeable side reaction that will be discussed later.

Equation (1) is just to show for those who don't know how one prepares mixed anhydrides (I) of *N*-protected amino acids and monoalkyl carbonates, followed by coupling with an amino acid or peptide ester (II). I would like to stress that an 0.5 molar excess of mixed anhydride is used in the coupling with the amine component (II). Activation time for making the anhydride is less than one minute in order to minimize racemization. We used ethyl acetate, tetrahydrofuran, and occasionally, dimethylformamide as solvents for preparing the anhydride. With the amino component, which will grow in our case to a octapeptide, all kinds of solvents can be used to obtain solutions, *e.g.* dimethylformamide.

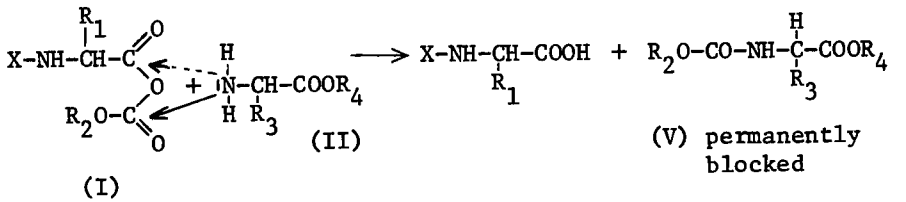
The unwanted side reactions are shown in Equations 2 and 3. You can get, at about 0°, disproportionation



Equation 1



Equation 2



Equation 3

(Equation 2) of the mixed anhydride (I) into symmetrical anhydride (III) and dialkylpyrocarbonate (IV). The dialkylpyrocarbonate will react with and block permanently the amine component. This disproportionation is negligible if one works at a temperature at or below minus 15°, and that is what we do in principle routinely. The formation of a symmetrical anhydride (III) is not all that bad because it gives the correct reaction, only you lose 50%.

Second comes a complication that is more troublesome (Equation 3): coupling on the wrong side of the mixed anhydride which will result in a permanently blocked urethane derivative (V). This reaction, in contrast to the disproportionation of the mixed anhydride, is not much temperature dependent; it depends mainly on steric factors. We circumvented this, as shown in Figure 1, by using fragment coupling.

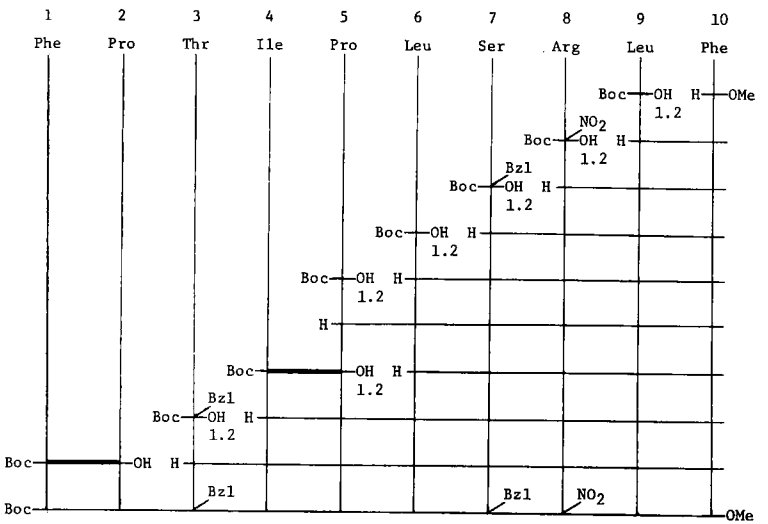


Figure 1: Synthesis of human growth hormone sequence 1-10 (HGH 1-10).

In our synthesis of the sequence 1-10 of HGH, all side-chains are protected: nitro on the arginine, benzyl on the serine and threonine. First we made the pentapeptide

6-10 by adding stepwise the amino acid, decomposing the excess anhydride with a $KHCO_3$-solution, and precipitating or extracting the peptide, followed by drying. One of the advantages of the method is that one can check on the purity of every intermediate product. The yield with isolation of all intermediates of the pentapeptide was 65%, and it went up to 75% with the repetitive procedure, that is, just precipitating, drying, and going on. This is not a very high yield, 75%, and this is mainly because coupling of Boc-nitroarginine gives minor by-products. After this we went on with the synthesis and found that with the isoleucine onto proline, and phenylalanine onto proline, it didn't work, we got coupling on the wrong side of the anhydride. We then coupled with the peptides drawn in heavy lines in Figure 1. These fragment couplings have the advantage inherent in proline-peptides of producing no racemization *via* the oxazolone mechanism. Without the isolation of intermediates it worked fine, and the overall yield of the pure decapeptide was 59%. I want to stress the fact that all the peptides shown in Figure 1 have been isolated too; all have correct elemental analysis for carbon, hydrogen, nitrogen; all optical rotations have been determined.

Finally it remained to prove that we really had made the decapeptide in optically pure form. We synthesized it, therefore, in another way, by a "classical" Merrifield synthesis on the polymer and split the decapeptide from the polymer by methanolysis.[11] Because for other reasons there was a Ztf protecting group on the threonine, these two decapeptides could not be compared directly. We therefore had to remove the protecting groups. Hydrogen bromide in trifluoroacetic acid gave a mixture of products. Liquid hydrogen fluoride gave much better results, and we could compare the decapeptide made by the two methods. The Merrifield peptide gave a correct amino acid analysis; its optical rotation was $[\alpha]_D^{24}$ -61° (*c* 0.8, 95% AcOH). The REMA-made HGH 1-10 showed $[\alpha]_D^{24}$ -50° *c* 0.8, 95% AcOH).

I would like to conclude that the repetitive mixed anhydride procedure is a very convenient method. It compares in the order of magnitude in speed with the Merrifield procedure; one can add to the growing peptide chain about one amino acid a day. The speed-limiting factor is mainly the drying time of the intermediate peptide, but complete dryness may not be absolutely necessary. The advantage,

like the repetitive syntheses by, for instance, Bodanszky *et al.*[12] and Morley[13] is that you can isolate and check on the properties of every intermediate. The disadvantage: it is still a lot of work. We haven't yet a machine to do the operations. And then, of course, you would ask, what is the limit of the method? We stopped because we started with the residue 10 for HGH, but being at residue 1, we felt we could have gone on more easily. In fact, in the beginning of the synthesis this gave some difficulties, because then you have small and rather soluble peptides that are not easily precipitated. In a later stage, after about three amino acids, then it goes much better. Frankly, I don't know, and at the moment we are trying to see how big a peptide we can make.

Acknowledgments

The investigation was carried out under the auspices of the Netherlands Foundation for Chemical Research (S.O.N.) and with support from the Netherlands Organization for the Advancement of Pure Research (Z.W.O). The experiments were performed by J. Floor and E. W. B. de Leer.

CHEMISTRY AND BIOLOGY OF PEPTIDES

STUDIES ON THE RATE OF RACEMIZATION AND COUPLING OF *N*-BENZYLOXYCARBONYLAMINO ACID AND PEPTIDE ACTIVE ESTERS

J. Kovacs, E. J. Davis, R. H. Johnson, H. Cortegiano, J. Roberts. Department of Chemistry, St. John's University, Jamaica, New York 11432

DURING THE SECOND AMERICAN PEPTIDE SYMPOSIUM, rates of racemization through α-hydrogen abstraction of several active ester derivatives of cysteine, glutamic acid and aspartic acid together with the rates of coupling of these active esters with valine methyl ester were reported.[1]

In order to establish the influence of the side chain of amino acids active esters on the rate of racemization and coupling, additional amino acids, namely phenylalanine, alanine, tryptophane and serine active ester derivatives were studied. The results of the rate studies are reported in Table I.

From the previous[1,2] and present kinetic data it was concluded that the side chain of a *N*-benzyloxycarbonylamino acid active ester has a significant effect on the rate of racemization under the conditions studied. This is indicated in Table II, which shows the ratios of racemization rate constants of *N*-benzyloxycarbonyl-*S*-benzyl-L-cysteine active esters, which is the fastest racemizing amino acid investigated so far, and *N*-benzyloxycarbonylamino acid active esters. The following order of decreasing rates was determined: cysteine > serine > aspartic acid > phenylalanine > glutamic acid > tryptophane > alanine. The racemization rates of the above *N*-benzyloxycarbonylamino acid active esters is in the following decreasing order: *N*-hydroxysuccinimidyl > pentafluorophenyl > 2,4,5-trichlorophenyl > p-nitrophenyl > pentachlorophenyl. This order is independent of the structure of the amino acid side chain.

Table II

Ratio of Racemization Rate Constants of *N*-Benzyloxycarbonyl-*S*-benzyl-L-cysteine Active Esters and *N*-Benzyloxycarbonylamino Acid Active Esters

Ester	*Cys / Ser*	*Cys / Asp*	*Cys / Phe*	*Cys / Glu*	*Cys / Ala*	*Cys / Trp*
OSu			35	109	280	
OPfp	16	13	40	97	405	330
OTcp(2,4,5)		19	41	205	270	
ONp		14	100	123	285	
OPcp	17	24	40	207	500	570

In contrast to racemization, the side chain of the above amino acid active ester derivatives has no significant effect on coupling with valine methyl ester. From Table I it can be seen that the greatest difference in coupling rates is between pentafluorophenyl and *p*-nitrophenyl esters; the former couples 80 to 400 times faster than the latter. The relative rates of coupling for the above amino acids decrease in this order: pentafluorophenyl > *N*-hydroxysuccinimidyl > pentachlorophenyl > 2,4,5-trichlorophenyl > *p*-nitrophenyl.

The decreasing order of coupling rate constants for the above active esters is not the same as the decreasing order for the racemization rate constants; this indicates that the "activity" of the ester is not strictly parallel with the racemization. This is best shown by the ratio of coupling to racemization rate constants which is also presented in Table I.

These ratios also indicate the relative extent of racemization which can be expected during coupling by the α-hydrogen abstraction mechanism. The larger this number the smaller the amount of racemization to be expected during coupling. The decreasing order of the ratios is the following: Ala > Trp > Glu > Phe > Asp > Ser > Cys; this indicates that there is a relationship between these ratios and the structure of the side chain of amino acids. The decreasing order of the ratios is the reverse of that for the rates of racemization. For alanine or tryptophane the ratios for all esters are very large and therefore the choice of active

ester for coupling or for the preparation of sequential polypeptides is not as critical as in the case of phenylalanine or especially in the case of cysteine.

For comparison the rate of racemization of *N*-benzyloxycarbonylglycyl-L-phenylalanine active esters were also studied under the same conditions, and the results are given in Table III.

Table III

*Average of two experiments.
†Estimated from 90% reaction time (about 1 min); the reaction is too fast to measure more than one point by the infrared technique employed.

It can be seen from Table IV that the rates of racemization of two *N*-benzyloxycarbonyl-*S*-benzyl-L-cysteine active esters are comparable[2] to those of the dipeptide active esters. This indicates that the racemization of *N*-benzyloxycarbonylcysteine active ester derivatives which is known to proceed through α-hydrogen abstraction may be as serious as the racemization of peptide active esters which is known to occur primarily through an oxazolone intermediate.[3,4]

Previously we presented experimental data which indicated that racemization of *N*-benzyloxycarbonyl-*S*-benzyl-L-cysteine pentachlorophenyl ester and *N*-benzyloxycarbonyl-L-phenylalanine pentachlorophenyl ester proceeds via isoracemization[5] in a non-polar solvent in the presence of triethylamine. In order to obtain more information concerning

Table IV

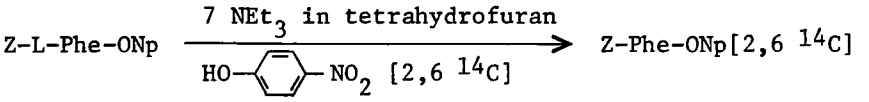
the reaction of triethylamine with amino acid active esters, labeled phenol exchange studies were initiated as indicated here:



The kinetic data for the incorporation of labeled p-nitrophenol are given in Table V. A tenfold increase in labeled phenol concentration did not increase the fraction incorporated; however, without added base there was negligible incorporation. Based on these preliminary studies, the rate of incorporation seems to be about 40 times faster than the rate of racemization under the same conditions. It may be concluded that the racemization of this active ester through α-hydrogen abstraction does not involve a ketene intermediate (E1cB mechanism); this was proposed earlier as a possible mechanism for the base catalyzed racemization of thiophenyl esters[6] of *N*-protected amino acids.

It is our conclusion that the presently available synthetic procedures are not refined enough to prepare large polypeptides in good yields and sufficiently pure form. Therefore, we believe that more investigations are needed to understand the kinetics of coupling reactions as well as the kinetics of racemization during coupling. These investigations should include a larger variety of activating and protecting groups as well as solvents and temperature.

Table V

Kinetic Data for the Triethylamine Catalyzed Incorporation of ^{14}C Labeled *p*-Nitrophenol into *N*-Benzyloxycarbonyl-L-phenylalanine *p*-Nitrophenyl Ester*

Time, min	*% ^{14}C labeled phenol incorporated*
10	27
20	41
40	52
60	61
150	78
240	90

*Concentration of Z-Phe-ONp was 0.05 *M*; concentration of labeled phenol was 2.85×10^{-4} *M*.

Presently the most widely used tests for racemization involve coupling with glycine ethyl ester; however, glycine couples much faster than the more hindered amino acids; consequently, more extensive racemization can be expected during coupling with any other amino acid.

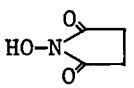
CHEMISTRY AND BIOLOGY OF PEPTIDES

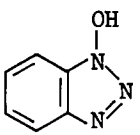
RACEMIZATION SUPPRESSION BY THE USE OF ETHYL 2-HYDROXIMINO-2-CYANOACETATE

Masumi Itoh. Research Laboratories, Fujisawa Pharmaceutical Co., Higashiyodogawa-ku, Osaka 532, Japan

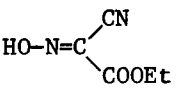
A COMBINATION OF DICYCLOHEXYLCARBODIIMIDE (DCC) with N-hydroxysuccinimide (I) has been recommended as a racemization free coupling reagent for peptides.[1,2] However, it is also known that I is not stable and that the combination of DCC and I occasionally leads to some side reactions.[3,4] Later 1-hydroxybenzotriazole (II) and its derivatives have been proposed as superior additive than I.[5] The author intended to search for more promising additives and alcoholic components of active esters, and now wishes to report the use of a strongly acidic oxime, ethyl 2-hydroximino-2-cyanoacetate (III), as a suitable additive for the same purpose.



(I)



(II)



(III)

III is a stable, acidic (pKa' 4.6) compound and is used in organic syntheses. Racemization with or without III was examined first by Anderson's test.[6] The coupling reaction of *N*-benzyloxycarbonylglycyl-L-phenylalanine with ethyl glycinate gave no racemate by the use of DCC and III in

tetrahydrofuran at room temperature, while the control experiment, without III, gave 8% of racemate. A comparison of additives, I, II, and III, was made by Bodanszky's test.[7] Coupling of *N*-acetyl-L-isoleucine and ethyl glycinate with DCC was carried out in dimethylformamide (DMF), in which significant racemization occurs. A typical procedure is as follows: ethyl glycinate hydrochloride (140 mg, 1.0 mmol) was dissolved in dry DMF (3.0 ml) and was neutralized with triethylamine (0.14 ml, 1.0 mmol) under ice-cooling. Then III (170 mg, 1.2 mmol), acetyl-L-isoleucine (173 mg, 1.0 mmol) and a solution of DCC (206 mg, 1.0 mmol) in DMF (2.0 ml) were added, in that order, into the above solution at 5°C. The mixture was allowed to react for 3 hr at 5°C and overnight at room temperature. After the complete evaporation of DMF the residue was dissolved in EtOAc and water. The EtOAc layer was washed with 5% $NaHCO_3$ solution, water, *N* HCl and water, and was dried over $MgSO_4$. Evaporation gave crude product, which was filtered with small amount of ether–petroleum ether mixture; 178 mg (69%).

For the calculation of racemization the crude product, ethyl *N*-acetylisoleucyl-glycinate, was hydrolyzed by 6*N* HCl at 110°C and subjected to amino acid analysis to detect D-alloisoleucine. About 0.7% of racemization occurred during hydrolysis of acetyl-L-isoleucine under the same conditions.

The results obtained are summarized in Table I, and show that I and III suppress racemization potently.

Table I

	Ac-L-Ile-OH (mmol)	*H-Gly-OEt.HCl (mmol)*	*Et_3N (mmol)*	*Additive (mmol)*	*Racemization (%)**
1	1.0	1.0	1.0	none	35
2	1.0	1.0	1.0	(I) 1.2	2.7
3	1.0	1.0	1.0	(II) 1.2	8.8
4	1.0	1.0	1.0	(III) 1.2	1.8

$$\text{*Racemization (\%)} = \frac{\text{Alloisoleucine} \times 100}{\text{Isoleucine} + \text{Alloisoleucine}}$$

Unexpectedly, II is less effective than I. Although this is incompatible with previously reported results by König and Geiger, a comparison is difficult because the racemate detection systems are completely different.

Apart from such a problem the combination of DCC with III seems to be a promising approach in coupling reactions.

Acknowledgment

The author expresses his deep gratitude to Dr. Miklos Bodanszky for his kind and helpful advice.

CHEMISTRY AND BIOLOGY OF PEPTIDES

RACEMIZATION OF *N*-METHYLAMINO ACID RESIDUES DURING PEPTIDE SYNTHESIS

John R. McDermott, N. Leo Benoiton. Department of Biochemistry, University of Ottawa, Ottawa K1N 6N5 Canada

FURTHER TO OUR WORK ON the synthesis of derivatives of *N*-methylamino acids,[1,2] we have initiated a study on the incorporation of *N*-methylamino acids into peptides. No systematic data are available in this area, and in particular, the supposed resistance of *N*-methylamino acid derivatives to racemization[3] has never been investigated quantitatively. We present results here which show that *N*-methylamino acid derivatives racemize as readily, and in some cases more readily, than the corresponding amino acid derivatives under conditions of peptide coupling and deprotection.

In preliminary experiments, it was found that Bz-MeLeu lost 90% of its optical activity after hydrolysis of the mixed anhydride formed during a 5-minute reaction with $Bu^{i}OCOCl$. Under the same conditions Z-MeIle and Boc-Ala-Pro were not racemized, whereas Z-Ala-MeLeu gave 27% of the L-D isomer. The extent of racemization in these three and subsequent experiments was determined by analysis of the diastereomeric products,[4,5] after suitable deprotection, with an amino acid analyzer. The several systems standardized and used in this study are described in Table I.

In the synthesis of standards, it was found that two widely used and relatively racemization-free reactions caused considerable racemization of *N*-methylamino acid derivatives. Saponification of Z-Ala-MeLeu-OMe gave 11%, and acidolysis of Z-Ala-MeLeu using 5.6 *N* HBr in acetic acid gave 17% of the L-D peptide. In addition, it was found that saponification of Z-MeIle-OMe gave 12% of the

allo isomer, and that a prolonged treatment of Z-MeIle with HBr in acetic acid gave 34% *a*MeIle. Under the same conditions, the corresponding derivatives of Ala-Leu and Ile gave less than 1% of the diastereomers. Pure L-Ala-L-MeLeu was finally obtained from both Boc-Ala-MeLeu-OBzl and Z-Ala-MeLeu-OBu^t using trifluoroacetic acid and hydrogenation for deprotection.

The extents of racemization obtained with various coupling methods for the condensation of Z- or Boc-Ala-MeLeu with Gly-OBzl are recorded in Table II, along with similar data for couplings using Z-Ala-Leu. In each case, the neutral product was isolated and analyzed after suitable deprotection. Essentially optically pure products were obtained only with the *N*-hydroxysuccinimide ester and with dicyclohexylcarbodiimide-*N*-hydroxysuccinimide (DCCI-HONSu)

and *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) *in the absence of salt*. The pronounced salt effect was not observed for the normal peptide coupling.

Oxazolonium salts have been proposed as intermediates in the racemization of *N*-methylamino acid derivatives,[6] and oxazolium-5-oxides (the conjugate base) have been prepared by heating *N*-substituted *N*-acylamino acids in acetic anhydride.[7] We have shown that such compounds can be formed under peptide coupling conditions (Z-Ala-MeLeu and DCCI in tetrahydrofuran for 10 min) by trapping the oxazolonium derivative in a 1,3-dipolar cycloaddition reaction[7,8] with methyl propiolate. The expected pyrrole, *N*-methyl,2-(1'-benzyloxycarbonylaminoethyl),3-methoxycarbonyl,5-isobutylpyrrole was obtained in 85% yield.

Promotion of oxazolone formation by chloride ion has been attributed to the basicity of the anion[9] and to the increased ionic strength of the solution.[10] Base catalysis

is unnecessary for cyclization to an oxazolonium cation, however, an increase in ionic strength of the medium could enhance formation of this derivative.

Racemization during couplings might also proceed by direct α-proton abstraction. *N*-Substituted *N*-methylamino acids are more prone to racemize by this mechanism than amino acid derivatives, as was shown by the racemization of Z-Ala-MeLeu-OMe and Z-MeIle-OMe during saponification. In *N*-monosubstituted amino acid derivatives, the -*N*-H group is generally more acidic than the α-*C*-H and so will ionize first, thus protecting the α-*C*-H from ionization. No such effect obtains for *N*-substituted *N*-methylamino acids.* Activation of the *N*-protected dipeptide with a strongly electron-withdrawing group will further increase the lability of the α-proton, and the basic chloride or tosylate anion may then be able to cause ionization.

*It is significant that MeIle-OMe racemized very little on saponification.

SYMPOSIUM DISCUSSIONS

Summarized by Johannes Meienhofer

SEVERAL COMMENTS AND QUESTIONS concerned the newly developed amine protecting groups (pp 315 to 323). The reductive cleavage of the isonicotinyloxycarbonyl group by Zn in acetic acid is easily achieved at room temperature, a system suitable for work with proteins. Tryptophan residues in S-protein seem not to be effected under these conditions, but, strangely, some oxidation was observed when the reaction mixture became aerated from too vigorous stirring. Mild oxidation by *m*-chloroperbenzoic acid in trifluoroacetic acid can be used to cleave the *N*-protecting 4,5-diphenyl-4-oxazolin-2-one (Ox) group (pp 321 to 323) thus providing a new selectivity. However, this reaction will not be applicable to sulfur-containing or other oxidizable peptides and, of course, proline or other imino acids cannot be protected by the "Ox" group.

A synthesis of luteinizing hormone-releasing hormone in which fragments were made from considerations of hydrophilicity *vs*. hydrophobicity (pp 325 to 329) was complimented by a discussant for the high yields achieved. Apparently, thin layer electrophoresis proved to be much superior to thin layer chromatography in assessing the homogeneity of intermediates in this synthesis. The biological assays were done by inducing ovulation in rats, rabbits, and hamsters.

The proposal of a complex between amine component and hydroxybenzotriazole ester (pp 343 to 350) in hydroxybenzotriazole-catalyzed active ester condensations appeared to be suggestive for *o*-nitrophenyl esters[1] as well. However, anchimeric assistance might also be an explanation for the superior properties of these esters (as remarked by Miklos Bodanszky). The *para*-nitrophenyl esters show (i) sometimes

slow reaction rates, (ii) incomplete reaction when sterically hindered, and (iii) a high solvent dependence (factor of 10), while the *ortho*-nitrophenyl esters show several times higher reaction rates, complete reaction even in some hindered conditions, and a much lower solvent dependence (factor of 2). These advantages should become especially apparent when ONo esters will be applied to solid-phase synthesis.

It was commented that pentafluorophenyl esters (used for a synthesis of human ACTH possessing the corrected structure,[2] pp 299 to 303) react very fast (20 min including work-up) and show the least racemization in chloroform and methylene chloride, followed by ethyl acetate and dioxane. In other solvents the racemization tendency is rather higher. | One should, of course, never use excess thiethylamine or any other *tert*-amine in active ester couplings, and the conditions used to study racemization (pp 359 to 364) are not recommended for a synthesis.

PROPERTIES OF ANTAMANIDE AND SOME OF ITS ANALOGUES

Theodor Wieland. Max-Planck-Institut für medizinische Forschung, Abteilung Chemie, Heidelberg, Germany

SUMMARY--Antamanide (AA), an antitoxic component was discovered in the lipophilic fractions of an extract of the green toadstool Amanita phalloides. It counteracts the toxicity of phallotoxins by preventing their accumulation in liver cells. The structure elucidation by mass spectrometry of peptide esters after partial methanolysis revealed a cyclodecapeptide *cyclo*(-Val-Pro-Pro-Ala-Phe-Phe-Pro-Pro-Phe-Phe) (I). Numerous analogues were synthesized by the solid-phase method and checked for antitoxic activity. A lipophilic side chain in position 1 is prerequisite of antitoxic activity. Replacing phenylalanine by tyrosine residues likewise leads to biologically active analogues The perhydrogenated I (HAA) has no protecting effect.

Antamanide and its biologically active analogues show in apolar solvents and in absence of Na^+-ions well marked negative dichroic absorption in the 220 nm region, which is shifted to positive values on adding polar solvents, particularly water, or Na^+-ions. The molecular change giving rise to this phenomenon manifests itself also in a blue shift of the UV absorption.

From spectroscopic titration (and ultrasonic absorption) experiments it is suggested that the molecule exists in two conformers. These are in equilibrium with each other, the ratio depending on the nature of the solvent, and the velocity of interconversion seems to be extremely high. The "polar" conformation (VIIb), which differs from the "apolar" VIIa by the number of intramolecular hydrogen bridges (4 to 6) forms of complexes with metals of radii of about 1 Å, thus preferring Na^+ over K^+. Na^+-Complex stability constants

are in correlation with antitoxic activity of I and its analogues. However, since HAA also forms a strong Na^+-complex, biological activity must be based on additional features of the molecule.

THE DEADLY POISONEOUS GREEN MUSHROOM Amanita phalloides contains toxic bicyclic peptides--the families of phallotoxins and amatoxins[1]--and, in addition, numerous lipophilic cyclopeptides. These can be extracted with ethyl acetate from aqueous solutions of strongly enriched material. Chromatographic fractionation of an analogous mixture obtained earlier in a different way[2] yielded a substance, which prevented the absolute lethal action of 5 mg of phalloidine per kg (LD_{50}=2.0 mg/kg) at the white mouse when given in a sufficiently high dose, simultaneously or a little earlier than the poison. Finally, this antitoxic substance could be obtained in crystalline state and showed its protecting power against 5 mg of phalloidine already at a dose of 0.5 - 1.0 mg/kg. A dose of 5 mg/kg of the antidote is sufficient for protection against 25 mg/kg of phalloidine. The substance has been called antamanide (AA).[3]

Biological Action

Using radioactively labelled phallotoxines and antamanide we got some insight into the mechanism of action of the antidote.[4] We found that death occurs in mice if the concentration of toxin in the liver exceeds *ca.* 30 µg/g. When antamanide is given to the animals 2 min prior to the toxin the amounts of toxin appearing in the liver are greatly reduced, Table I. The uptake of the toxin by the organ can

Table I

also be shown in an isolated rat liver preparation. Already 10 minutes after addition of the labelled toxin more than 90% have been absorbed by liver cells. The toxin is not metabolized; after homogenization nearly the whole radioactivity can be extracted with methanol, and identified with the unaltered compound by thin layer chromatography.[5] As a consequence of phallotoxin poisoning K^+-ions begin to flow out of the cell together with some enzymes, *e.g.* β-glucuronidase. The rate of absorption of the toxin as well as the leakage of membrane is strongly diminished by antamanide, as shown in Figure 1. The phenomenon points

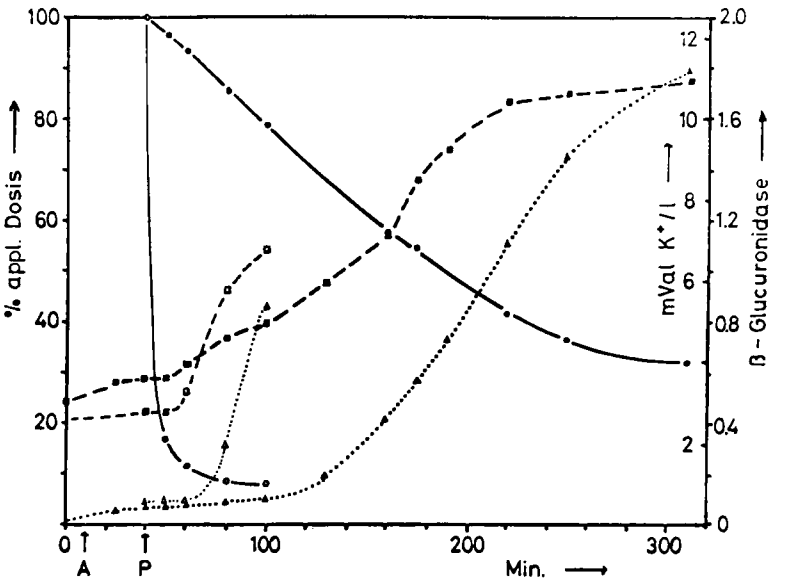

Figure 1: Inhibition of absorption of ^{3}H-desmethylphalloin (P, -o-), K^+ release (-□-), and efflux of β-glucuronidase (-Δ-) in a perfused rat liver preparation by antamanide (AA). 5 mg AA were added to 100 ml perfusion medium 30 min before 250 µg (55 µCi) ^{3}H-desmethylphalloin. to a competition for one and the same receptor site of antamanide and phallotoxin. Experiments with a ^{14}C-containing derivative of antamanide, however, disproved such an assumption. Mice were given a high dose of

phalloidin and shortly afterwards a certain amount of labelled antamanide. Their livers did not contain less of the label than livers of control animals, which had not received the poison (Table II). This proves that antamanide is not bound to the receptor sites competent for the toxin. Therefore, its action must be sought in a rather specific membrane tightening effect.

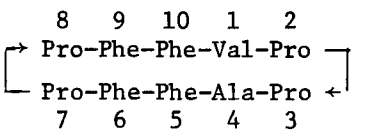
Structure Elucidation

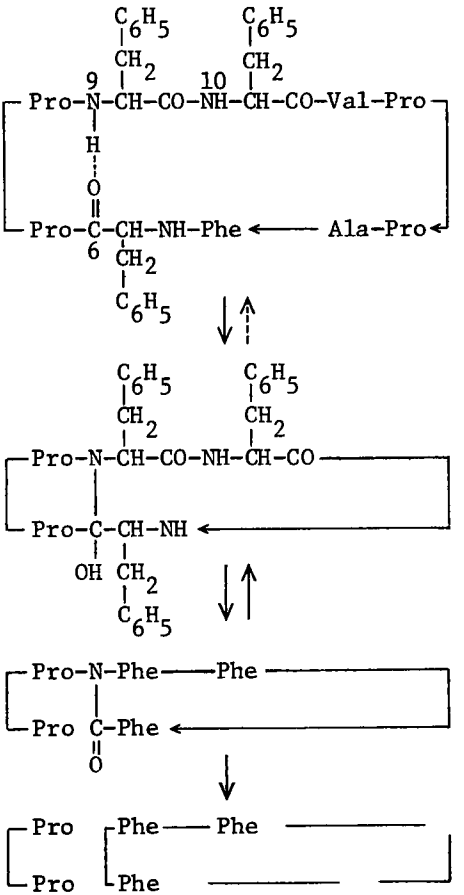
AA is a cyclic decapeptide containing the amino acids L-alanine, L-valine, L-phenylalanine and L-proline in a ratio of 1:1:4:4.[3] The structure elucidation was carried out mainly by partial methanolysis, gas chromatographic separation of the trifluoroacetylated peptide methyl esters and their mass spectrometric analysis[6] and resulted in the structural formula I.



I

Of some interest for peptide chemists is the observation of "wrong" amino acid sequences among the fragments of

partial methanolysis as, *e.g.* Tfa-Phe-Phe-Phe-OMe although in I only two phenylalanine residues are in sequence. The presence of triphenylalanine is probably the result of an intermediate cyclol formation in a transannular reaction. Interaction of the NH hydrogen of Phe^9 with the carbonyl of Phe^6 forms an orthoamide structure followed by transpeptidation to generate the sequence of 3 phenylalanines, Scheme I.



Scheme I

Syntheses of Antamanide and Some of its Analogues

The synthesis of I can be carried out by cyclization of ten different linear decapeptides. We have chosen mostly the sequence 6,7-→4,5 and prepared the decapeptide Phe-Pro-Pro-Phe-Phe-Val-Pro-Pro-Ala-Phe at first by classical methods,[7] and then[8] by the solid-phase technique of Merrifield. The decapeptide 5 → 4 has been synthesized by others.[9] Cyclization with the use of dicyclohexylcarbodiimide and *N*-hydroxysuccinimide gave 30-40% of I. Gram quantities of the linear decapeptides can now be prepared within 30 hours in an automated peptide synthesizer (Schwarz BioResearch) using the conventional or a novel reactor system.[10]

The relatively easy access to the cyclic decapeptide made it possible to synthesize a great number of analogues of antamanide to investigate the structural details necessary for the biological action of the molecule. At first the single amino acids 1-valine and 4-alanine have been substituted by several other amino acids[11] including the unusual constituent L-α-aminobutyric acid (Abu).[12] The results of these investigations are summarized in Table III and in Figure 2. It appeared that the lipophilic nature of the side chain of residue 1 is most essential. Valine can be replaced by leucine or isoleucine without loss of antitoxic activity. If a three-carbon chain is present in position 1, the structure of residue 4 is not very critical since the [Gly^4] analogue still possesses appreciable activity. The amino acid residue in position 4 can even be omitted and the resulting cyclic nonapeptide (XXVI in Table IV) still possesses activity. However, reduction of the number of C atoms in the side chain of Val^1 gives much less potent or even inactive analogues. Benzyl side chains in positions 1 and 4 apparently abolish the antitoxic activity.

The [Ala^1,Val^4] analogue, L-*retro*-AA (No. XII in Table III) could not be tested, because it immediately precipitated from its solution in DMSO on adding the required amount of water. The same happened with its mirror antipode, D-*retro*-AA, which was synthesized in my laboratory by B. Penke.[13] The difficulty was overcome by introduction of a solubilizing group as will be mentioned later. D-Antamanide, the enantiomer consisting of the D-amino acids in the correct sequence has been synthesized in Yu. A. Ovchinnikov's laboratory and, independently, in ours. It has about 10% of the antitoxic activity of AA.

XVI	Val	Phe(Val^6)	1,5	C_2 Symmetry

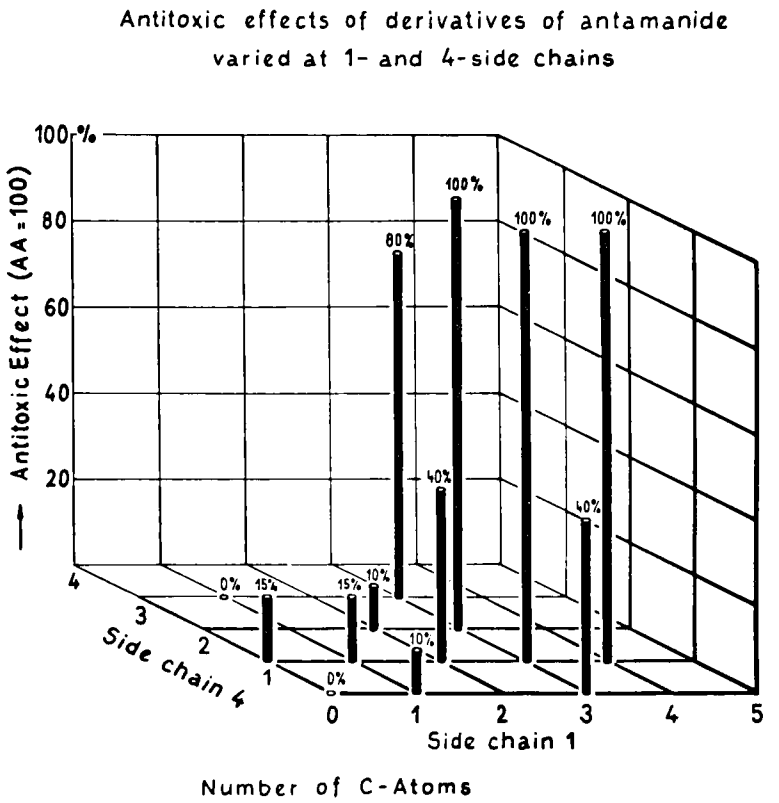

Figure 2: Influence of side chains length of amino acids in positions 1 and 4 of antamanide on antitoxic effectivity

The almost symmetrical molecule of AA offers several possibilities for conversion into entirely symmetrical analogues. By replacing Ala^4 by Val, or Val^1 by Ala, two molecules have been synthesized (III and IX, respectively, in Table III) which happen to be identical with their respective *retro*-forms. For obtaining C_2-symmetry in each of them only an exchange of amino acids 4 for 6 was necessary. Since the [Val^4] analogue (III) is about 10 times more active than IX, we synthesized analogue XVI and found that it had relatively high protecting potency, at a dose of only 1.5 - 2 mg/kg.[14]

Analogue III

C_2 symmetric XVI

Perhydro-AA (HAA) was obtained by hydrogenation of AA over Pt-catalyst in glacial acetic acid in Ovchinnikov's group and, simultaneously, in our laboratory.[15] The compound which contains four residues of cyclohexylalanine instead of phenylalanine has an extremely low solubility in solvents containing water and, perhaps as a consequence, exhibits no antitoxic activity.

Very active analogues of AA are obtained by replacing one of the four phenylalanines by tyrosine. The [Tyr^6] analogue XVIII, Table IV, has been synthesized by Ch. Rietzel[16] *via* classical methods of peptide chemistry using Boc-Tyr(OBzl). The other tyrosine-containing analogues were prepared by Ch. Birr using the solid-phase technique.[17]

Table IV

Tyrosine-Containing Analogues of Antamanide (I), of Some Ile and Gly Containing Analogues of the des-Ala^4-Homologue

No.	*Amino Acids in Position* 1 2 3 4 5 6 7 8 9 10	*Protecting Dose*

XXIV	*cyclo*(-Gly ————Gly-Tyr——————)	>20
XXV	*cyclo*(-Gly————Gly——Tyr——————)	>20
XXVI	*cyclo*(——————des——————Tyr——)	5-10

The [Tyr^5] and [Tyr^6] compounds, XVII and XVIII, as well as the [Ile^1,Tyr^5] analogue XXII have equal protecting effectiveness as AA (I). [Tyr^9]-AA and [Tyr^{10}]-AA (XIX and XX) are markedly less active; and activity is also reduced by introduction of more than one Tyr (XXIII). Analogue XXI which contains four tyrosine residues is not protective even with doses up to 10 mg/kg.[18] The tyrosine-containing [Gly^1,Gly^4] analogues, XXIV and XXV, exhibit (as XIII) no antitoxic effect.

The phenolic OH groups are in different micro environments in each of the four mono-Tyr analogues which show different spectral behaviour in UV in alkaline methanolic solution, Figure 3. The phenolate curves of [Tyr^5]- and

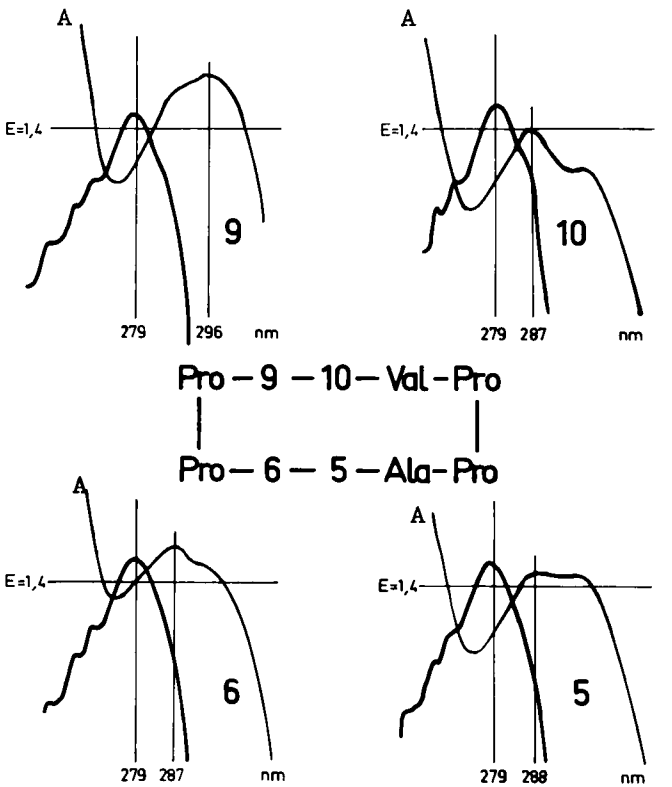

Figure 3: UV absorption spectra in neutral and alkaline (A) methanolic solution of the four different Tyr analogues of antamanide

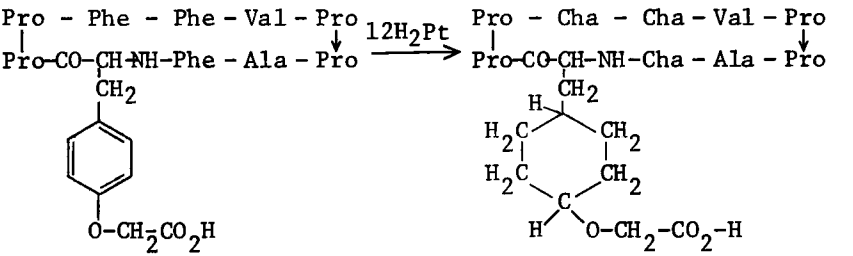
[Tyr^6]-AA have still some similarity, but differ markedly from [Tyr^9]- and [Tyr^{10}]-AA which again are different from each other in shape, maxima, and extinction.

Using the phenolic hydroxyls as a handle it was possible to introduce groups into the molecule, which lend good water-solubility to the otherwise very slightly soluble compounds.[19] The monoesters of sulfuric or phosphoric acid of XVII and XVIII or their *O*-carboxymethyl- or *O*-3-sulfopropyl derivatives form water soluble neutral alcali metal salts, which have antitoxic effects comparable to the mother compounds. Strikingly, only in the sulfopropyl ether of XVII the activity is reduced by 90%.

It was this solubilizing effect, which enabled us to test also a D-*retro* species of AA.[13] [D-Tyr^6]-all-D-*retro* AA which is nearly insoluble in the biological testing system was solubilized as Na^+ salt of its sulfuric acid ester, which was antitoxic at a protecting dose of 2 mg/kg. Assuming that it is also the poor solubility of perhydro-AA (HAA), which causes its ineffectivity as an antitoxin, the carboxymethylated [Tyr^6]-AA was hydrogenated over Pt to obtain a water soluble derivative. The desired product, [cyclohexylalanyl^{5,9,10},4-carboxymethoxycyclohexylalanyl^6]-AA could indeed be isolated.[20] Its NH_4^+-salt was readily soluble in water, but had also no antitoxic effectivity up to 10 mg/kg.



[*O*-Carboxymethyl-Tyr^6]-AA

Product of perhydrogenation (Cha = cyclohexylalanyl)

Metal Complexes of Antamanide and Analogues

AA interacts with Na and K ions. This was shown in Shemyakins and in our laboratories by mass spectrometry (occurrence of an ion AA·Na^+), IR spectroscopy (increase of carbonyl absorption at 1630 cm^{-1} in the presence of Na^+), potential measurements with ion specific glass electrodes, vapor pressure osmometry, ORD-spectrometry and decrease of

electrical conductivity of ethanolic NaCl solutions in the presence of AA.[21] We have now extended these investigations by comparing the reaction of several metal ions with AA and some of its structural analogues.[22] We also used the solvent extraction method of Pedersen,[23] in which the amount of metal picrates extracted from aqueous solutions by AA dissolved in CH_2Cl_2 corresponds to complex formation. For alcali ions and alcaline earth ions we found the values given in Table V. Evidently, ions of *ca.* 1 Å radius are

Table V

Alcali and Alcaline Earth Picrates Extracted from Aqueous Solution by Antamanide in Methylene Chloride

Rb	1.48	0.3	Ba	1.35	0.7
Cs	1.67	0.2			
NH_4		0.5			

much preferred by AA. Analogues devoid of antitoxic activity extracted little or none of the Na picrate. More quantitative spectroscopic assays on complexation capacity with several cations were also performed. The ORD spectrum of AA in 96% ethanol has two rather large negative Cotton effects between 200 nm and 220 nm, whose magnitude and shape depend on the nature of the solvent and the presence of cations.[21] This pertains also to the CD spectra where AA exhibits a very strong negative dichroic absorption at 224 nm in dioxane and in other non-polar solvents, whereas a positive band is observed at about the same wave length region in the presence of water or of Na ions.[24] Methanol also causes a positive shift, but not to the same extent as water (Figure 4). Thus the positive shift of ellipticity at 224 nm produced by several metal ions could be utilized as a measure of complexing activity. In Figure 5, the

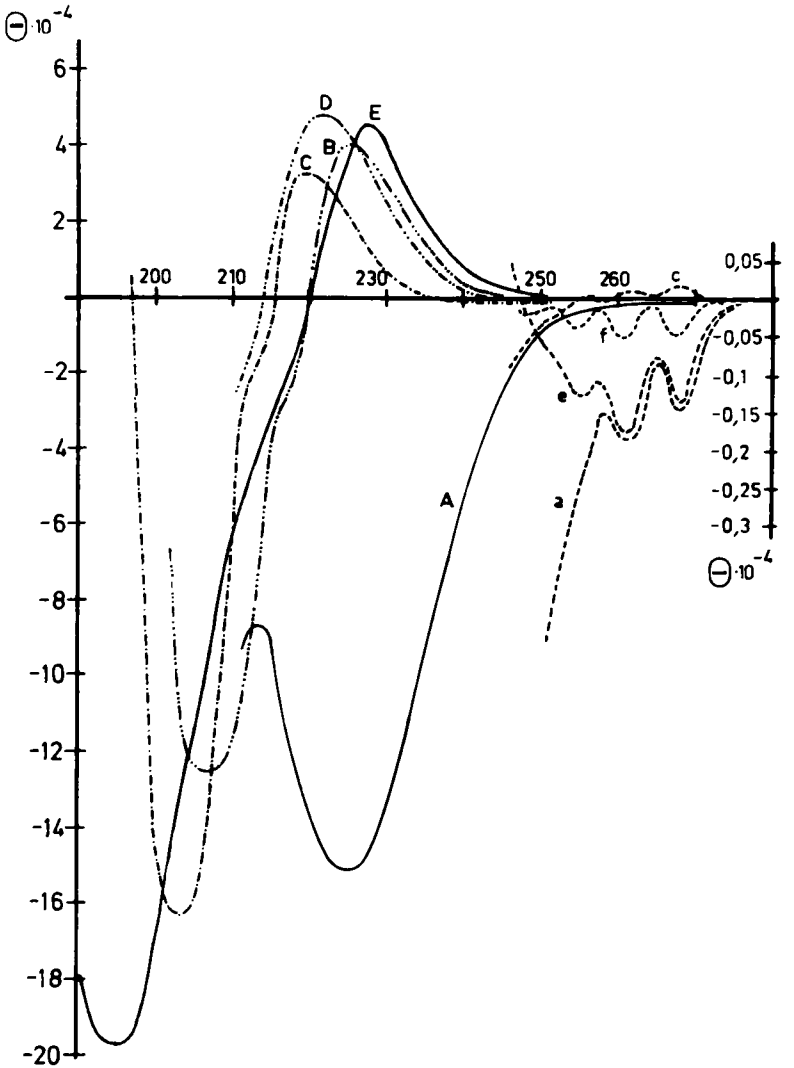

Figure 4: CD spectra of antamanide in various solvents, and in the presence of Na^+ ions. a, A, in dioxane; e, E, in methanol-water (1:1). B, Antamanide and Na^+ (1:15) in dioxane; c, C, in methanol, D in acetonitril. f, $AA \cdot NA^+$ (1:1) in acetonitrile.

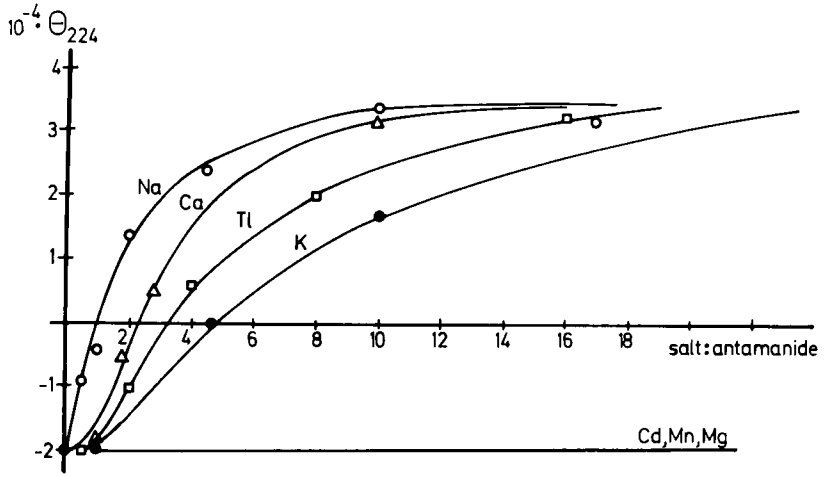

Figure 5: Positive shift of molar ellipticity of antamanide (Θ) at 224 nm ($4{,}35 \cdot 10^{-3}M$ in methanol) caused by increasing amounts of different metal ions.

positive shift of molar ellipticity of AA is depicted in response to increasing concentrations of several cations. Here again Na and Ca formed the most stable complexes. Half complexation in methanol was found in $3.4 \cdot 10^{-3}M$ AA solution at a molar ration of Na/AA = 1.5:1, for Ca at 3:1, for K at 7:1, and surprisingly also for Tl at 4.5:1. No spectral changes were caused by Cd (r, 0.97 Å), Mn(II) (r, 0.80 Å) and Mg (r, 0.66 Å).

Complexation of the AA molecule manifests itself also in UV spectra, because the interaction of the complexing cation with the n electron of the peptide carbonyl oxygen shifts the $n-\pi^*$ transitions to shorter wave lengths. This effect can be seen also in the 250 nm region of the spectrum where the absorption decreases with increasing ion concentration. The complex stability constants of AA with Na^+, K^+ and Ca^+ were determined in solvents of different polarity by this spectrophotometric titration method and compared with analogous values obtained by vapor pressure osmometry and ion-selective glass electrodes. Some of the values obtained are summarized in Table VI. High values of K (strong complexing), are found in the more lipophilic solvents like acetonitril or ethanol. In methanol- or water-containing acetonitrile or ethanol the values are lower by 1-2 orders of magnitude. Solvents with high affinity to the cations and to the complexing carbonyl oxygen atoms,

Table VI

Stability Constants (K) of AA Complexes in Different Solvent Systems

	CH_3CN	$CH_3CN \cdot H_2O$ (96:4)	$CH_3CN \cdot H_2O$ (92:8)	$C_2H_5OH \cdot H_2O$ (96:4)	$C_2H_5OH \cdot H_2O$ (30:70)	CH_3OH
Na	$3 \cdot 10^4$	$2{,}6 \cdot 10^3$	$1{,}2 \cdot 10^3$	$2{,}0 \cdot 10^3$	0	$5{,}0 \cdot 10^2$
K	$2{,}9 \cdot 10^2$	$2 \cdot 10^1$	$2{,}8 \cdot 10^2$	$1{,}8 \cdot 10^2$	-	10^1
Ca	$1{,}0 \cdot 10^5$	-	-	-	-	$3 \cdot 10^1$

especially water and low alcohols, diminish complex stabilities; thus in 70% water-containing ethanol no complexation at all was observed. Indeed, it is in lipophilic environment, that the most stable Na-complex is formed. The crystalline perchlorate of $AA \cdot Na^+$ could be obtained by adding $NaClO_4$ to a 0,1% solution of AA (I) in methanol.[22]

The selectivity of AA for Na^+ over K^+, which is essentially the consequence of a steric adaption of the cyclopeptide to a certain ion size is maintained throughout the different solvents, but it changes quantitatively due to the different solvation energies. One finds values of *ca.* 100 for the ratio K_{Na}/K_K in acetonitrile, but decreased selectivity in more polar solvents (*e.g.* 10 in 4% H_2O-containing ethanol).

As mentioned above, addition of water (or methanol) to AA in non-polar solvents caused changes in CD spectra that are quite similar to those caused by Na^+-complexation. This similarity also applies to UV spectra, in which not only complex forming ions (see above), but also strong polar agents, particularly water, bring about a blue shift of the carbonyl adsorption, presumably by formation of H-bonds. This manifests itself in a decrease of absorbancy in the region of the phenyl absorption, which could be used for a spectrometric titration of 248 nm of AA with water. In Figure 6 the extinction of 248 nm of AA in 1,4-dioxane or acetonitril is plotted against increasing water concentration and a parallel (positive) change of molar ellipticity at 224 nm. The sigmoidal shape of the curves points to the transformation of one conformer more stable in lipophilic solvents to a second one which is stable in presence of water. The situation reminds us of the reaction

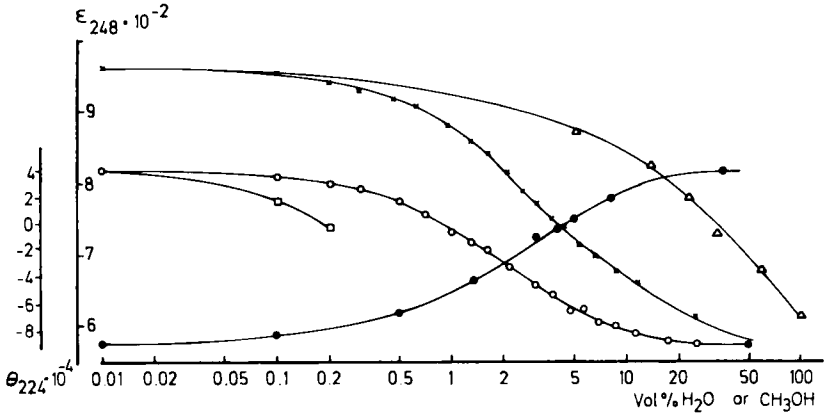

Figure 6: Decrease of absorption at 248 nm and increase in molar ellipticity (Θ) at 224 nm of antamanide ($10^{-3}M$) in different solvents on addition of water or methanol; Δ methanol in 1,4-dioxane, x water in 1,4-dioxane, • water in acetonitrile (• = Θ), □ water in CH_2Cl_2.

of AA with Na^+-ions. A conformation equilibrium of only two species dependent on polarity has already been suggested from the existence of an isosbestic point in the ORD spectra by Ivanov *et al.*,[24] and was recently confirmed by ultrasonic absorption measurements.[25] It was suggested that the interconversion of the two conformers is a very fast process which happens within microseconds while the complexation reaction takes milliseconds.

Structural Analogues

Some of the structural analogues mentioned earlier have been investigated with respect to the magnitude of the negative Cotton effect[26] and their complexing behavior (Table VII).[22] In all analogues so far studied, negative rotation, complexation capacity and biological activity are attributes of the molecules which parallel each other. This argues in favor of an ionophoric mechanism of AA action. From perhydrogenated AA (HAA), however, we learned that Na complexation can not be the only prerequisite of antitoxic activity. HAA forms a Na complex as stable as AA itself, but does not protect against phallotoxins.[16] Since its CD spectrum also resembles that of AA in all solvent mixtures its molecular structure is assumed to be not very different

Table VII

Molar Rotation Φ_{240} and Na^+-Complex Stability Constants (K_{Na}) in Ethanol-Water (96:4) as Related to Protective Doses of Analogues of Antamanide (see also Table III)

Analogue	$\Phi_{240} \cdot 10^{-4}$	K_{Na} *(1/mole)*	*Protective dose against 5 mg phalloidine (mg/kg)*

HAA	-9,0°	~ 2000	> 20

from AA. The argument of slight solubility in biological systems as an explanation for the lack of antitoxic activity seems invalid since a soluble *O*-carboxymethyl compound likewise was not protective. Therefore we compared the selectivity of AA and HAA for Na^+ over K^+ and found that HAA is a relatively good complexing agent also for K^+-ions: K_{Na}/K_K in acetonitrile-H_2O (96:4) is *ca.* 100 for AA and only 10 for HAA. Differences in affinities to water as compared with Na^+ may thus play a role in the mechanism of biological action.

Conformation of Antamanide

The conformation of the Na-complex of AA has been described by the Moscow Academy group,[24] who used ORD, NMR and IR data for the structure analysis in solution. Recently, minimum energy calculations by Tonelli *et al.*[27] based on NMR and CD led to a proposal for the conformation

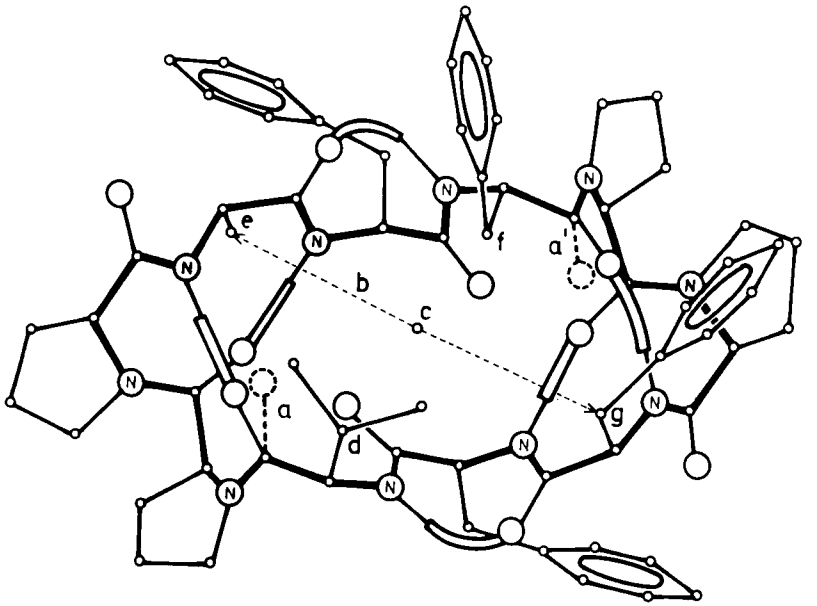

Figure 7a: Conformation of antamanide in nonpolar solvents.[22]

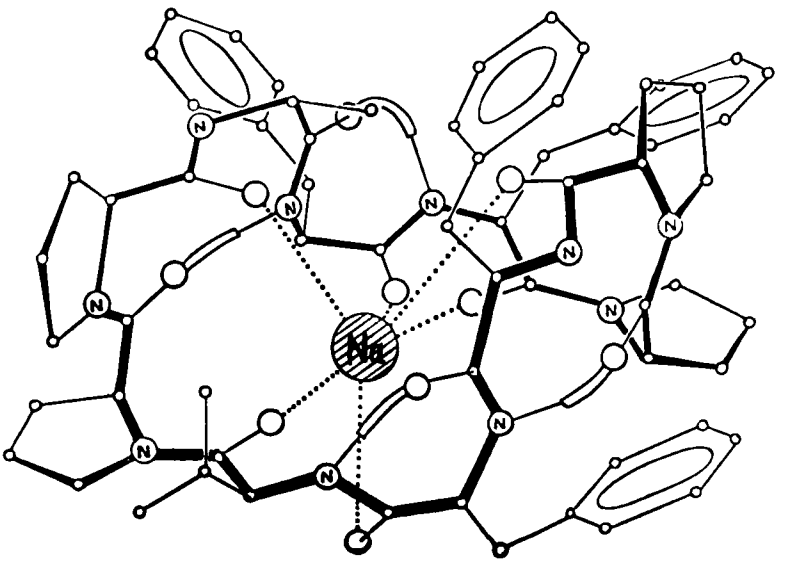

Figure 7b: Conformation of the Na^+-complex of antamanide (independent of nature of solvent). [From Ivanov *et al.*[24]]

of uncomplexed AA in nonpolar solvents. From NMR studies of exchange with deuterated alcohols in $CDCl_3$ solution it was concluded that the peptide NH resonances were not hydrogen bonded and accordingly a conformation was suggested. The spectral changes seen in AA solutions when polar solvents, particularly water, are added, were interpreted as solvent effects. It has been pointed out, however, on page 392 that from spectroscopic titration experiments with water and ultrasonic absorption measurements a conformational transition rather than solvent effects have to be considered.[28] This transition process, occurring already in the presence of tiny amounts of water or methanol, is very fast. Thus, the high exchange rate of some protons which led to the disproval of H bridges and the sharp average signals actually found in the spectrum[27] may find an explanation.

The unusually high negative dichroism at about 230 nm of AA in nonpolar solvents (Figure 4) is attributed[28] to $n\rightarrow\pi^*$ transition of two transoid tertiary amide groups distorted out of plane. These are the bonds between Pro^3-Ala^4 and Pro^8-Phe^9 (Figure 7a). Two additional intramolecular H-bridges are formed between NH of Phe^9 and CO of Phe^6 and between NH of Ala^4 and CO of Val^1 in favor of out of plane deformations of 20-30° of the two carbonyls concerned. By H^+ containing solvents or by complexing metal ions these bridges will readily be abolished thus converting the molecule to the structure of Figure 7b, in which, according to Ivanov *et al.*[24] the Na^+ ion is held in an octahedral *O*-complex. For *cis*-prolyl-peptide bonds in AA, as ascertained by ^{13}C-nmr Fourier transformation confer the paper of F. A. Bovey (p 3).

CHEMISTRY AND BIOLOGY OF PEPTIDES

ON THE SYNTHESIS OF SCOTOPHOBIN: A SPECIFIC BEHAVIOR-INDUCING PEPTIDE

Wolfgang Parr, Günther Holzer. Chemistry Department, University of Houston, Houston, Texas 77004.

SUMMARY--Seryl-asparagyl-asparaginyl-asparaginyl-glutaminyl-glutaminyl-glycyl-lysyl-seryl-alanyl-glutaminyl-glutaminyl-glycyl-glycyl-tyrosylamide was synthesized via the solid phase method. In biological and analytical tests, the peptide is identical with scotophobin, a specific behavior inducing pentadecapeptide, that was isolated from the brain of rats which were trained to have fear of dark.

IN 1968 UNGAR *ET AL.*[1] SHOWED that dark avoidance could be induced in mice or rats by injection of a brain extract which was taken from rats that were trained to fear the dark. Using this behavior as basis for a bioassay an active material, named scotophobin, was isolated from the brains of 4000 trained rats.[2,3] Scotophobin has been formulated as a pentadecapeptide with the sequence I given in Figure 1. The structure determination was done by means of mass spectrometry[4] however the functionalities of the amino acids in position 2, 5 and 11 remained uncertain. Since no more natural material was available only the synthesis of the possible analogs could clarify the structure of scotophobin. Sequence IV was synthesized by Ali *et al.*[5] This peptide had 2.5% (75 U/mg) biological activity and its R_f values on thin layer plates did not agree with those of natural scotophobin.

We first synthesized structure III,[6] peramidoscotophobin, which possessed 10-12% (300 U/mg) of the activity of the natural material. However, its analytical data differed

I	Ser-	Asx-	Asn-	Asn-	Glx-	Gln-	Gly-	Lys-	Ser-	Ala-	Glx-	Gln-	Gly-	Gly-	$TyrNH_2$

Figure 1: Synthetic analogs of scotophobin. I represents the amino acid sequence deduced by mass spectrometry. Amino acids in position 2, 5, and 11 are uncertain in terms of their functionality. Sequences II, III, and IV were synthesized. Biological and chemical properties of sequence II are identical with those of the natural peptide.

from those of natural scotophobin. Both structures IV and III could now be rejected.

In our second synthetic approach we chose structure II[7] in which Asn in position 2 is replaced by Asp. The protected pentadecapeptide resin ester Boc-Ser(Bzl)-Asp(OBu^t)-Asn-Asn-Gln-Gln-Gly-Lys(Z)-Ser(Bzl)-Ala-Gln-Gln-Gly-Gly-Tyr(Bzl)-resin ester was synthesized by the method of Merrifield[8] using an automatic peptide synthesizer.

The *t*-butyloxycarbonyl (Boc) group was used to protect the α-amino group of all amino acids except for Asp which was protected by the 2-(*p*-biphenyl) isopropyloxycarbonyl (Bpoc) group.[9] The following derivatives of the protected amino acids were used: Tyr(Bzl), Asp(OBu^t), Lys(Z), Ser (Bzl). Coupling of Gly, Ala, Ser, Lys and Asp was achieved at room temperature with dicyclohexylcarbodiimide (DCC). Methylene chloride was used as solvent. Gln and Asn residues were coupled as *p*-nitrophenyl esters in dimethylformamide (DMF). Boc-amino acids and Boc-amino acid nitrophenyl esters were used in six fold excess. For the incorporation of the amino acids in position 12(Gln), 11(Gln), 9(Ser), 8(Lys), 6(Gln), 5(Gln), 4(Asn), 3(Asn), 2(Asp) and 1(Ser) the coupling reaction was repeated. Reaction times were 3-5 hr for DCC condensations and 8-12 hr for *p*-nitrophenyl ester couplings. Three different deblocking reagents were used for effective removal of the Boc group. Residues 15, 14, 13, 10, 9 were deblocked with 3*N* HCl in dioxane-CH_2CL_2 (1:1), residues 8, 7, 3 with HCl saturated CH_2Cl_2-TFA (1:1) and residues 12, 11, 6, 5, 4 with CH_2Cl_2-TFA (1:1). The

Bpoc group of Asp was deblocked with acetic acid-formic acid-H_2O (7:1:2). Reaction times for the removal of Boc groups varied between 30 min and 60 min. The removal of the Bpoc group was achieved in 3 hr. The amount of free amino groups were determined by titration after deblocking[10] and after coupling.[11] Unreacted amino groups were acetylated after each coupling step in order to prevent the formation of failure sequences.[12] A graphical representation of yields in the coupling steps is given in Figure 2.

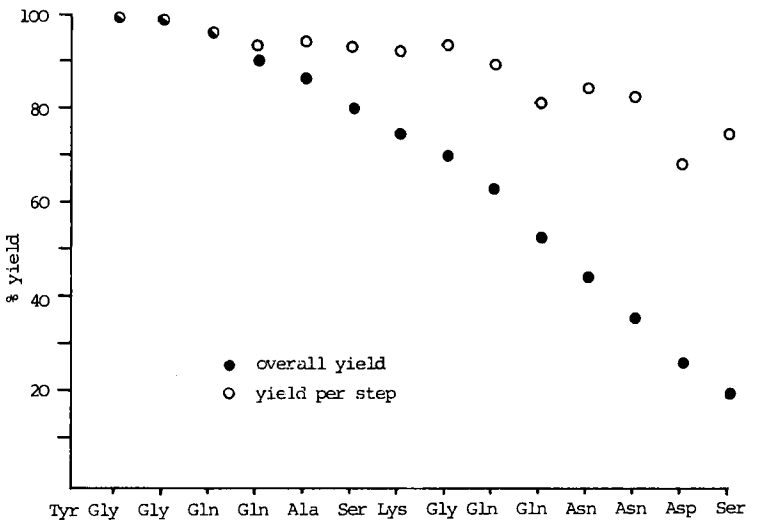

Figure 2: Yields per step and overall yields in the synthesis of sequence II. After each coupling step the unreacted amino groups were determined with pyridine-HCl in methylene chloride. The free chloride was titrated according to the method of Volhard. The amount of Tyr bonded to the resin was taken as 100%.

Starting with 4.5 mmol Boc-Tyr(Bzl) resin ester (the chloromethylated beads were purchased from Schwarz/Mann, New York, capacity: 3.7 mmol/g), the following cycles were used to build the pentadecapeptide. Removal of the α-amino protection group, 12 washing steps, neutralization with Et_3N-$CHCl_3$ (1:9) for 10 min, 9 washing steps, coupling in

CH_2Cl_2 or DMF, 10 washing steps, determination of non-reacted amino groups with 0.1*N* pyridine HCl in CH_2Cl_2 for 20 min, 12 washing steps, neutralization with Et_3N-$CHCl_3$ (1:9) for 10 min, 8 washing steps, acetylation (if the coupling step was not repeated) with 15 ml DMF, 1.2 ml acetic acid anhydride, 0.5 ml Et_3N, 8 washing steps. Washing solvents were used in 30 ml portions and reagents in 15 ml portions. A three way solenoid valve activated by the relay control directed the waste to a collecting vessel in which the titrations were done. The cleavage of the protected pentadecapeptide from the resin was achieved by direct ammonolysis.[13] The *t*-butyl ester provides an ammonia resistant protection for Asp under the conditions applied [liq. NH_3-DMF (1:1), room temperature, 7 days]. The crude protected pentadecapeptide amide was treated for 2 hr with HF-TFA at 20°C. After evaporation of the solvent 3.8 g of crude peptide was obtained. A portion of this material (900 mg) was purified by gel filtration on Sephadex LH-20 using MeOH as solvent. Further purification was achieved by preparative thin layer chromatography on silica gel plates. Three ninhydrin positive spots were obtained. The spot at R_f 0.57 was eluted with pyridine-acetic acid buffer. By this procedure 180 mg of pure peptide was obtained. Amino acid analysis gave the following molar ratios: Asp 2.85, Ser 1.80, Glu 3.85, Gly 3.00, Ala 1.00, Tyr 1.10, Lys 0.95, NH_3 7.20.

In Table I chromatographic and biological data of synthetic peptide II are compared with those of natural scotophobin. Both peptides showed similar R_f values on thin layer chromatography (tlc). After microdansylation[14] the synthetic peptide II and the natural material appeared as single spots on tlc and had corresponding R_f values. For further identification a tryptic digestion was performed. The resulting two fragments had similar R_f values on tlc. The biological activity of the synthetic peptides was tested on mice. Only animals which spent 90 sec out of 180 sec in the dark box were selected for injections. In these tests peptide II is identical with the natural material. Furthermore, the dose response shows no significant difference in activity between synthetic peptide II and natural scotophobin. The potency ratio was found to be 1.11 and the slope ratio 1.09. These results have since been confirmed by other laboratories.[15-18] On the basis of these analytical and biological data it is highly probable that scotophobin is a peptide of structure II.

Table I

Comparison of Chromatographic Properties and Biological Activities of Natural Scotophobin and Synthetic Peptide II

	Natural Scotophobin (I)	*Synthetic Peptide (II)*	*Solvent System*
R_f Values	0.58	0.57	*n*-Butanol-Ethanol-Acetic Acid-Water 80:20:10:30
Dansyl-derivatives			
1. Dimension	0.16	0.16	Formic Acid-Water 1.5:100
2. Dimension	0.16	0.18	Benzene-Acetic Acid 9:1
Tryptic Fragments			
T_1	0.26	0.30	*n*-Butanol-Ethanol-Acetic Acid-Water 80:2-:10:30
T_2	0.40	0.37	
Biological Activities	3000.U/mg*	3000.U/mg	

*One unit of activity is the amount of material that reduces the mean time spent in the dark from 130 to 60 sec.

CHEMISTRY AND BIOLOGY OF PEPTIDES

TUFTSIN, THREONYL-LYSYL-PROLYL-ARGININE, THE PHAGOCYTOSIS STIMULATING MESSENGER OF THE CARRIER CYTOPHILIC γ-GLOBULIN LEUCOKININ

Paul S. Satoh, Andreas Constantopoulos, Kenji Nishioka, Victor A. Najjar. Division of Protein Chemistry, Department of Molecular Biology and Microbiology, Tufts University School of Medicine, 136 Harrison Avenue, Boston, Massachusetts 02111

IN PREVIOUS COMMUNICATIONS from this laboratory a naturally occurring[1,2] phagocytosis stimulating tetrapeptide, tuftsin, was shown to be covalently bonded to a specific γ-globulin fraction, leucokinin.[3] It is released by a specific enzyme present on the outer surface of the polymorphonuclear (PMN) neutrophil.[1] This peptide is responsible for all the phagocytosis stimulating activity of leucokinin. No other peptide shows that effect.[1,2] Trypsin also releases tuftsin from leucokinin rich phosphocellulose fraction (PC) IV.[2,4,5] Tuftsin activity is detectable only in the H chain of leucokinin. The tetrapeptide has recently been identified in the Fc fragment of the H chain.[6]

The Isolation of Tuftsin

This has been accomplished by leucokininase derived from human, dog and rabbit neutrophil membrane preparations as well as by crystalline trypsin.[1,2] The amino acid analysis yielded unit values for threonine, lysine, proline and arginine and its sequence proved to be Thr-Lys-Pro-Arg. This was accomplished through the use of leucine aminopeptidase (LAP) and the dansyl method[7] for the amino-terminal end and carboxypeptidase B (CP-B) and tritium exchange[8] for

the carboxy-terminal. Tuftsin was synthesized by the solid phase method[9] and proved to be identical with the natural product in all physical, chemical and biological parameters.[2]

The Covalent Bond Between Tuftsin and the Carrier γ-Globulin

Tuftsin is at the carboxy-terminal end of either the nicked segment of it, or a branch off that chain. The evidence was derived from the use of LAP and CP-B, both of which destroy the biological activity of free tuftsin.[2] Six samples of fraction PC IV prepared from Cohn II and six samples from fresh human γ-globulin were reacted with LAP and with CP-B. Each sample was then treated with leucokininase to release tuftsin. Tuftsin activity was then tested by its ability to stimulate phagocytosis. The phagocytosis values calculated for (a-f) samples as percent of reagent controls, were as follows: CP-B treated Cohn PC IV values were (a) 85, (b) 105, (c) 110, (d) 90, (e) 95, (f) 103 - averaging 98; while the LAP treated samples were 200, 200, 185, 190, 205, 205 respectively - averaging 198. Similarly, CP-B treated fresh γ-globulin PC IV were (a) 100, (b) 98, (c) 87, (d) 100, (e) 115, (f) 95 - averaging 99; while the same samples treated with LAP were 220, 205, 190, 200, 195, 210, respectively - averaging 203. These results indicate that the carboxy-terminal arginine is free and the tetrapeptide is bound at the amino-terminal. This conclusion was further strengthened by the liberation of the arginine residue by CP-B treatment.

Until pure leucokinin is obtained, the exact nature and location of tuftsin on the Fc portion of the H chain can not be defined with certainty. It appears that tuftsin is linked, at least in part, through the hydroxyl of the amino-terminal threonine. Several lines of evidence favor the ester bond linkage. (a) γ-globulin was thoroughly dialyzed in five changes of 40 volumes of 8 *M* urea followed by 0.15 *M* NaCl and water. It was then treated with 2 *M* hydroxylamine for one hour at room temperature.[10] After deproteinization, the hydroxylamine salt was separated on Sephadex G-10. It was then chromatographed on G-25 in 1 *M* acetic acid. The effluent between Kav 0.34-0.40 was subsequently chromatographed on Aminex.[2] The peptide yielded approximately unit ratios of Thr 0.98, Lys 1.0, Pro 0.86, Arg 1.1. It was subsequently chromatographed on silica gel. The peptide gave the exact R_f values as the enzymatically isolated tuftsin in two chromatographic systems. Sequence analysis also yielded

the same tetrapeptide. CP-B digestion liberated arginine. The remaining tripeptide incorporated ^3H from ^3H_2O only in proline, 532 counts per minute per *n* mole. For further confirmation, the tetrapeptide was dansylated and yielded identical R_f values in three systems as authentic tuftsin. On hydrolysis it yielded N^{α}-dansyl-threonine and N^{ϵ}-dansyl-lysine. CP-B treatment of the dansylated peptide followed by dansylation of the product, yielded dansyl-arginine and a dansylated polypeptide with the same R_f as synthetic N^{α}-dansyl-threonyl-N^{ϵ}-dansyl-lysyl-proline. Tritium incorporation from ^3H_2O into this polypeptide was found only in proline, 547 counts per minute per *n* mole. Thus the sequence is Thr-Lys-Pro-Arg. The yield on hydroxaminolysis amounted to 10% of the tetrapeptide present. (b) Thoroughly dialyzed γ-globulin in 6 *M* guanidine HCl, was dansylated[7] and then subjected to hydroxaminolysis as above. Dansyl tuftsin was readily identified on thin layer chromatography with a yield of 18%. Acid hydrolysis yielded N^{α}-dansyl-threonine and N^{ϵ}-dansyl lysine. CP-B treatment yielded arginine as carboxy-terminal. The low yield in both instances (a and b) is to be expected because of the O → N shift under the conditions of high pH. Similar low yields were obtained by hydroxylamine treatment of serine and threonine peptidyl esters of rearranged protamine. These were shown to result from O → N shift.[11] (c) Trypsin readily released tuftsin in the presence of 50% 2-chloroethanol. Under these conditions, peptidase activity of trypsin is destroyed and only esterase activity is preserved.[12]

The existence of tuftsin as a molecular entity is suggested (a) by the specificity of the carrier molecule and the presence of a specific enzyme for its release. (b) Postsplenectomy leucokinin is devoid of activity.[4] (c) Human mutants have been identified in several families who are defective in tuftsin activity.[1,5]

It is of particular interest that the complete sequence of γG_1 (EU) myeloma protein shows the same tetrapeptide in the Fc fragment of the heavy chain, residues No. 289-292.[13] Assuming its presence in normal γG_1, it is unlikely that this is the direct source of the tetrapeptide. (a) Tuftsin is a carboxy-terminal peptide of, or within, the Fc. The reported activity of Fab[10] and its absence in Fc was due to leucokinin contamination of Fab and the lack of binding of Fc to the cell membrane. (b) Not all γG_1 carry tuftsin activity.[4,5] PC I-PC III contain about 94% of the γG_1 of the serum and these are inactive.[4,5] The only active fraction, PC IV, contains a small quantity of γG_1. (c) Splenectomized humans

possess γG_1 in the normal range, 10 mg per ml, yet all fractions, including PC IV are devoid of activity.[4,5] (d) γG_1 levels in cases of the tuftsin deficiency syndrome are within the normal range averaging 10.07 mg per ml of serum.[4,5] (e) Myeloma protein of the γG_1 type was devoid of even traces of activity. (f) Once activity is removed by trypsin, the carrier molecule does not release further activity upon treatment with leucokininase.[2] (g) Tuftsin is released by NH_2OH. (h) Incubation of fresh serum at 37° for 1-2 hours destroys tuftsin[4] presumably because of the presence of CP-B like enzyme.[14] Trypsin in 50% 2-chloroethanol loses its peptidase, but retains its esterase activity, yet is still capable of quick release of tuftsin. These data put together make it unlikely that tuftsin derives from the tetrapeptide of the Fc fragment of γG_1 as an intact part of the polypeptide chain unless it is ruptured[15] at the carboxy-terminal arginine by a specific enzyme. All the data are consonant with the presence of a carboxy-terminal tetrapeptide fragment and probably esterified at the amino-terminal.

If indeed the tetrapeptide is present both within some, and terminal in other H chains, it would not be unique in serum proteins. Two types of low molecular weight human kallidinogens exist, one has the kinin, methionyl-lysyl-bradykinin, at its carboxy-terminal, and the other has the same kinin fragment in its internal structure.[16] More relevant is the demonstration that in high molecular weight bovine kininogen-I methionyl-lysyl-bradykinin moieties are located both at the carboxy-terminus and inside of the polypeptide chain.[17]

Should it turn out that the same tetrapeptide is present within the Fc fragment of normal γG_1 species, it may indeed have biological significance in furthering enhanced phagocytosis and pinocytosis. Tuftsin, as a carboxy-terminal peptide of leucokinin, could be released by leucokininase as the trigger mechanism that initiates the act of phagocytosis. γG_1 of the plasma bearing the tetrapeptide within the Fc piece, would be taken up in the phagocytic vacuole and provide another source of tuftsin within the cell. This may explain the observation that "once a leucocyte has ingested one or more particles, it becomes phagocytically more active than a resting cell." In keeping with this fact is the well-known tendency of a relatively small proportion of the granulocytes in an acute bacterial lesion to accomplish most of the phagocytosis.[18]

CHEMISTRY AND BIOLOGY OF PEPTIDES

BIOLOGICALLY ACTIVE POLYPEPTIDES FROM THE LUNG

Sami I. Said, Satoshi Kitamura. University of Texas (Southwestern) Medical School and Veterans Administration Hospital, Dallas, Texas

Viktor Mutt. Karolinska Institute, Stockholm

THE WORK TO BE PRESENTED HERE was prompted by the finding that extracts of fresh lung contained soluble vasoactive materials, some of which appeared to be protein or polypeptide in nature.[1]

Our efforts to isolate a vasoactive polypeptide from hog lungs have led to the extraction and partial purification of two biologically active peptide fractions, which are dilators of peripheral systemic and pulmonary vessels, and have activity on non-vascular smooth muscle.

The extraction work was carried out at the Karolinska Institute, and the biological characterization was done at the V.A. Hospital, Dallas, and The University of Texas (Southwestern) Medical School.

Extraction and Purification

Fresh lung was collected in the abbatoir from hogs which had just been killed. The lungs were kept on ice during quick transfer to the laboratory, where they were sliced into thin slices and submerged in boiling H_2O for ten minutes, to destroy proteolytic enzymes. The boiled lungs were then minced and extracted in dilute acetic acid and the extract was filtered until clear. Concentration of the peptides from this extract was accomplished by a sequence of procedures adapted from those used in the isolation of gastrointestinal polypeptides.[2,3] These procedures were: adsorption on

alginic acid and subsequent elution with 0.2 *M* HCl, precipitating out the peptides by saturating the eluate with NaCl, extraction of this salt precipitate with methanol at neutral pH, followed by precipitation with ether at a low pH, and a second procedure of salting out.

To isolate the peptides in question from the methanol extract, two further purification steps were carried out: 1) chromatography on a column of Sephadex G-25 fine, developed in 0.2 *M* acetic acid buffer (Figure 1); and

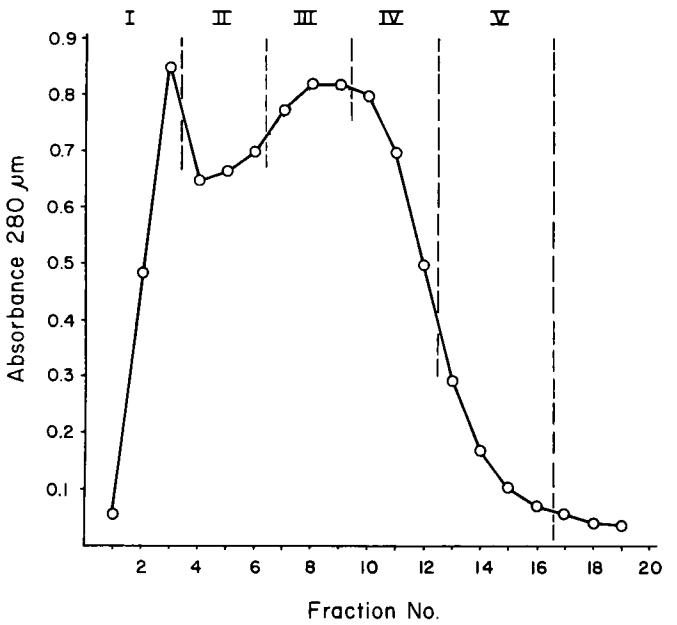

Figure 1: Chromatography of methanol extract of hog lung on Sephadex G-25, fine, in 0.2*M* acetic acid. Column dimensions: 95 x 3 cm. Fractions (11 ml) collected q 5 min. after void volume of 167 ml.

2) ion-exchange chromatography, on a column of carboxymethyl cellulose, developed in 0.02 *M* and 0.2 *M* NH_4HCO_3.

The last chromatography resulted in the elution of at least two peptide peaks (Figure 2), (A) which was eluted with the weaker buffer, and (B) which was eluted with the

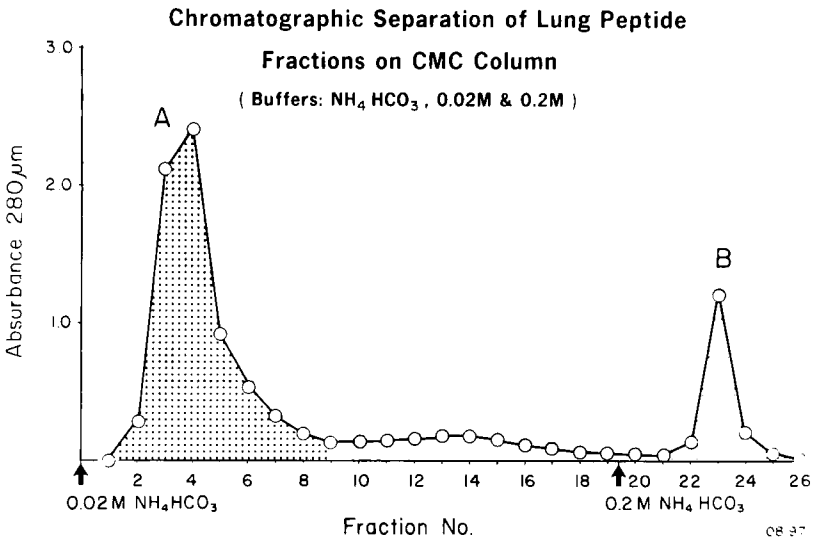

Figure 2: Chromatography of fraction IV from Sephadex column on CMC, in 0.02 *M* and 0.2 *M* NH_4HCO_3. Column dimensions: 25 x 1. Fractions (4 ml) collected q 10 min. after void volume of 5.5 ml.

stronger buffer. A third fraction, emerging in between, was not investigated further. Approximately 10 kg of fresh lung was required for the extraction of 1 mg of fraction B.

Bioassay

Throughout the purification steps, the bioassay we employed was based on peripheral vasodilator activity, measured as the ability of each preparation to increase the femoral arterial blood flow in anesthetized dogs. The flow was measured by a non-cannulating probe (Carolina Medical Electronics), placed around one femoral artery; saline solutions of each fraction were infused into a superficial branch of the same artery. Systemic (aortic) blood pressure was recorded simultaneously, to permit estimation of changes in femoral vascular resistance.

Biological Activity

We examined three aspects of biological activity of the lung peptides: systemic vasoactivity, evaluated by measuring femoral arterial blood flow and aortic blood pressure; pulmonary vasoactivity, determined by infusing the peptide fractions into isolated lobes of dog lung, perfused with Krebs-dextran at constant flow, and measuring perfusion pressure; and activity on non-vascular smooth muscle, tested by adding the peptide fractions to several isolated smooth-muscle organs, superfused with Krebs solution.

1. Systemic Vasodilator Effect

Infusions of approximately 6 μg/kg of the peptide fractions for one minute caused peripheral vasodilation, as evidenced by considerable increases in femoral arterial blood flow, with little or no fall in systemic arterial blood pressure. In some instances, the blood pressure actually *increased* slightly (5-10 mm Hg) while femoral flow increased (Figure 3). The femoral vasodilation was

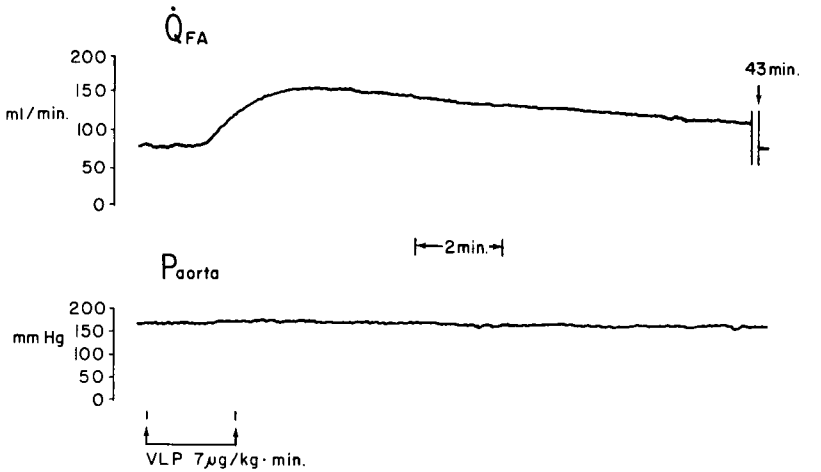

Figure 3: Simultaneous records of mean femoral arterial blood flow (Q_{FA}) and mean aortic blood pressure (P_{aorta}) in anesthetized dog, showing the effect of infusion of lung peptide (Sephadex fraction II). Infusion was given for two minutes.

prolonged (at least 40 minutes) with fractions II and III from the Sephadex column, but relatively brief (3-6 min) with fractions IV and V.

The absence of systemic hypotension with the increase in peripheral blood flow distinguishes this peptide from the recently isolated Vasoactive Intestinal Polypeptide (and from most other vasodilators), and suggests that other vascular beds may be constricted while extremity vessels are dilated.

2. Pulmonary Vasodilator Effect

In six experiments on isolated, perfused lung, lung peptide fractions A and B, given in doses of 100 μg/min, produced about the same fall (2 mm Hg) in perfusion pressure as 10 μg of isoproterenol or of acetylcholine. However, the vasodilation caused by either peptide fraction was several times as prolonged, lasting for up to 25 minutes, as opposed to 3 or 4 minutes for the other compounds.

3. Activity on Non-Vascular Smooth Muscle Organs

When tested on isolated guinea-pig trachea, continually superfused with Krebs solution, both fraction A and fraction B relaxed the trachea.[4] When we added another smooth muscle tissue, rat stomach strip, it became evident that fractions A and B contained *two distinct* principles, since A contracted rat stomach while B relaxed it (Figure 4).

Possible Role in Normal Function or Disease

The extraction of biologically active polypeptides from the lung naturally raises the questions: What role, if any, do they have in the normal regulation of the airways and pulmonary vessels? Are they normal local "tissue" hormones or could they be released into the circulation? How effective may they prove to be as therapeutic dilators of bronchi and of pulmonary vessels? These and other questions must await full purification of the active peptides and the development of sensitive assays for them.

CHEMISTRY AND BIOLOGY OF PEPTIDES

L-(N^5-PHOSPHONO)METHIONINE-*S*-SULFOXIMINYL-L-ALANYL-L-ALANINE, AN ANTIMETABOLITE OF L-GLUTAMINE PRODUCED BY A STREPTOMYCETE

James P. Scannell, David L. Pruess, Thomas C. Demny, Helen A. Ax, Florence Weiss, Thomas Williams, Arthur Stempel. Chemical Research Department, Hoffmann-La Roche Inc., Nutley, New Jersey 07110

IN RECENT YEARS, largely as a result of a deliberate search for antimetabolites,[1-3] several biologically active di- and tripeptides have been isolated from fermentation broths.[4-10] We wish to report here the isolation and structural elucidation of a new member of this series, L-(N^5-phosphono) methionine-*S*-sulfoximinyl-L-alanyl-L-alanine, I.

The substance is produced by an unclassified streptomycete species and inhibits the growth of *Serratia sp.* on a chemically defined minimal medium.[11] The growth inhibition is relieved by addition of L-glutamine to the medium. The fermentation conditions, microbiological assay and isolation procedure will be described in detail elsewhere.[12]

Characterization of I

After a 5 step 10,000 fold purification analytically pure I was deposited slowly as amorphous spherules from methanol-water solution; mp 192° dec. Elemental analysis gave correct data for $C_{11}H_{23}N_4O_8PS$. The NMR spectrum is similar to that of the dephospho compound II described below. The IR spectrum (KBr, 1 mg) contained peaks at 3000, 1650 and 1020 cm^{-1} which may be attributed to $-NH_3^+$, $-\overset{O}{\overset{\|}{C}}-O^-$, and S=O[13] groups respectively, but a peak at 1200 cm^{-1} assigned[13] to the unsubstituted S=N group in II and III was not present in I or V.

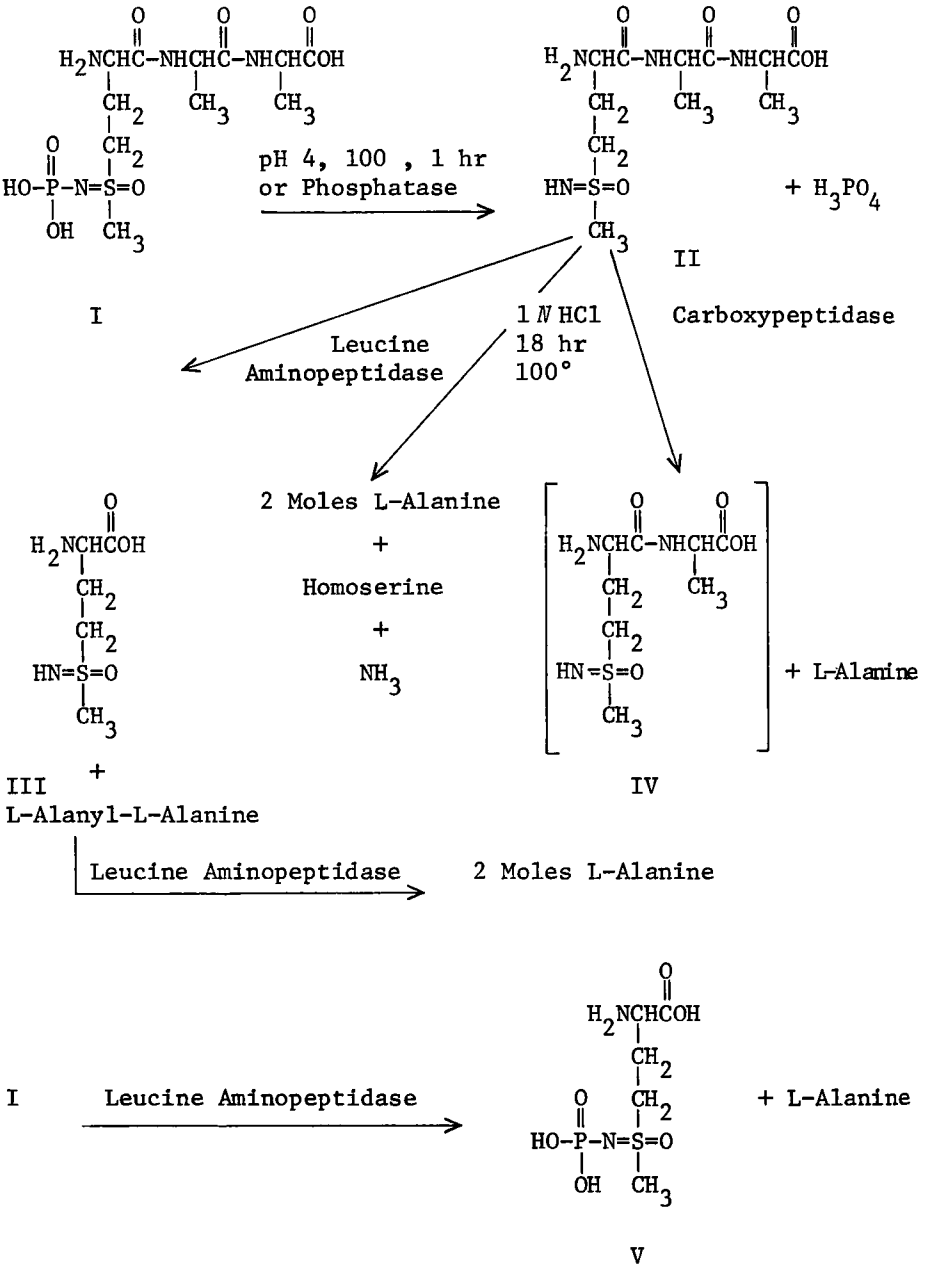

Figure 1: Degradation of L-(N^5-phosphono)methionine-*S*-sulfoximinyl-L-alanyl-L-alanine (I).

Chemical and Enzymatic Conversion of I to II

Dephosphorylation to II was effected by maintaining an aqueous solution of I at pH 4 and 100° for 1 hr (1/2 life-10 minutes) or by the enzymatic action of intestinal or *E. coli* alkaline phosphatase. The quantitative release of phosphate was followed by the method of Fiske and Subba Row.[14] N^5-Phosphonomethionine sulfoximine, V, prepared either synthetically[15] or by enzymatic degradation of I (see below) was hydrolyzed chemically and enzymatically at essentially the same rates. Purification of II was accomplished by absorption onto AG50WX4 (50-100 mesh in the H^+ form), elution with 10% aqueous pyridine, evaporation at reduced pressure and crystallization from methanol: mp 204-206°; NMR (20 mg, D_2O, ext TMS, both 60 and 100 Hz spectra with decoupling experiments) δ 1.79, 4.57 (A_3X, 4, J=7Hz, CH_3CH), 1.85, 4.82 (A_3X, 4, J=7Hz, CH_3CH), 3.62 (s,3, CH_3S), 3.92, 2.85, 4.75 (AA'MM'X, 5, CH_2CH_2CH). Elemental analysis gave correct data for $C_{11}H_{22}N_4O_5S$. The properties of II prepared by action of *E. coli* alkaline phosphatase were identical to those reported above for II prepared by chemical dephosphorylation.

Strong Acid Hydrolysis of I or II

Treatment of either I or II with 5.0 *N* HCl at 100° for 3 hr released 2 mol of L-alanine (quantitation by amino acid analyzer; structure by isolation and crystallization as described below; absolute configuration by optical rotation) and roughly equivalent amounts of NH_3 (Nesslers reagent) and methionine sulfone or sulfoxide (vpc of TMS derivative). Small amounts of alanyl-alanine were detected (vpc of TMS derivative) during the course of the reaction. In 1 *N* HCl at 100° up to 18 hr, alanine and NH_3 were released with alanylalanine as a transient intermediate, but the major degradation product of the methionine sulfoximine portion of the molecule was homoserine (vpc of TMS derivative of lactone and free acid).

Leucine Amino Peptidase Degradation of II

A solution consisting of 132 mg II and 1.3 mg preactivated leucine amino-peptidase (Miles Laboratory) in 19 ml 0.01 *M* $MgCl_2$ was incubated at pH 8.4 and 25°C for 3 1/2 hr. The solution was then added to the top of a column (2.5 cm x 19 cm) which contained 75 ml AG50WX4

resin (200-400 mesh in the Na^+ form). The column was eluted first with 700 ml 0.2 *M* sodium phosphate-citrate buffer[16] pH 2.9 then with 300 ml of the same buffer adjusted to pH 4.8. Alanine and methionine sulfoximine were detected at elution volumes 400 to 650 and 800 to 900 ml respectively. Each amino acid was desalted by readsorption on AG50WX4 (50-100 mesh in the H^+ form) followed by elution with 10% aqueous pyridine and evaporation at reduced pressure. Alanine was crystallized from 80% aqueous ethanol. Yield 37 mg (52%); mp 296°; $[\alpha]_D^{25}$ +12.4° (*c* 1, 5 *N* HCl) lit.[17] +14.6°, but we obtained +12.53° for an authentic sample. Elemental analysis gave correct data for $C_3H_7NO_2$.

Methionine sulfoximine, III, was crystallized from 80% aqueous ethanol in two crops, 17 mg (23%); mp 240°; $[\alpha]_D^{25}$ +33.3° (*c* 1, 1 *N* HCl). Lit.[18] for 2(s), S(s) isomer; mp 239°; $[\alpha]_D^{25}$ +34°; for 2(s), S(R); mp 235°; $[\alpha]_D^{25}$ +39.0°. IR (KBr) essentially identical to that of synthetic III (racemic at S). Elemental analysis gave correct data for $C_5H_{12}N_2O_3S$.

When the enzymatic hydrolysis was carried out with relatively less enzyme, substantial amounts of alanylalanine were detectable (vpc of TMS derivative and Technicon amino acid analyzer) during the course of the reaction.

Leucine Amino Peptidase Degradation of I

A solution of 18 mg pre-activated leucine amino peptidase and 100 mg I in 37 ml 0.05 *M* $MgCl_2$ was incubated at pH 8.4 for 5 hr at 25°C. The solution was then applied to a column which contained 45 ml AG50WX4 (100-200 mesh in the H^+ form). N^5-Phosphonomethionine sulfoximine, V, was washed off the column with water and after evaporation at reduced pressure, an amorphous preparation of V was obtained which had the same tlc mobility and essentially the same IR (in DMSO) as synthetic V (racemic at sulfur). This compound was synthesized by the method of Rowe *et al.*[15] modified by the introduction of a base hydrolysis step (15 min, 60°, 0.1 *M* NaOH) to ensure removal of protecting groups. The product has the properties described by Rowe *et al.*[15] except that we obtained mp 183-185° (dec) compared to 149-152° cited.

End Group Analysis of II

Alanine was shown (tlc and vpc of TMS derivative) to be liberated when 800 μg II in 1 ml 0.025 *M* tris HCl buffer pH 7.5 containing 0.5 *M* NaCl was treated with 5 μg

carboxypeptidase A (Worthington Biochemical) for 4 hr at 25°C. Prior to chromatography it was necessary to desalt the hydrolysate by the AG50W-pyridine elution technique described above. Another product of the reaction which had a long retention time during vpc and which, like II, gave a yellow reaction product with ninhydrin but which had a tlc mobility different from II, was presumed to be IV.

After II was subjected to dansylation and hydrolysis by the method of Hartley and Grey,[19] the dansyl derivative of methionine sulfoximine but not that of alanine was shown to be present by electrophoresis and tlc.

Discussion

The composition of II follows unambiguously from (1) the elemental analysis; (2) the release of 2 mol of L-alanine from acid hydrolysates; (3) the recovery of L-methionine-*S*-sulfoximine in the leucine amino peptidase hydrolysate; (4) the previously known[20] strong acid hydrolysis of methionine sulfoximine to homoserine, methionine sulfone and methionine sulfoxide. That the amino acids are in a linear peptide array is shown by the susceptibility to enzymatic attack and the presence of $\overset{+}{N}H_3$ and $\overset{O}{\overset{\|}{C}}-O^-$ groups (IR, electrophoresis and method of purification). Dimeric or polymeric structures are ruled out by the absence of required intermediates during enzymatic hydrolysis. The peptide sequence is demonstrated by the end group analyses and the release of alanylalanine as a transient intermediate during acid and leucine amino peptidase hydrolysis. The location of the phosphate group in I is demonstrated by lack of a reasonable alternative ($\overset{O}{\overset{\|}{C}}-O^-$ and $\overset{+}{N}H_3$ unsubstituted as shown by IR and electrophoresis) and the direct analogies to the IR and rates of chemical and enzymatic dephosphorylation of V.

The reversal by L-glutamine of the antibacterial activity of I is not surprising since methionine sulfoximine is a known inhibitor of glutamine synthetase[21] and it has been shown[22] that in the process of inhibition methionine sulfoximine is phosphorylated by the enzyme to the N^5-phosphono compound which is then irreversibly bound to the active site of the enzyme.

The remarkably similar bacterial product,[10] phosphinothricyl-L-alanyl-L-alanine, VI, is also an inhibitor of glutamine synthetase.

CHEMISTRY AND BIOLOGY OF PEPTIDES

A COMPARISON OF THE STRUCTURAL AND FUNCTIONAL PROPERTIES OF NERVE GROWTH FACTOR AND INSULIN

*Ralph A. Bradshaw, William A. Frazier, Ruth Hogue Angeletti.** Washington University School of Medicine, Department of Biological Chemistry, St. Louis, Missouri 63110

SUMMARY--The data presented on the similarity of the effects of insulin and nerve growth factor (NGF) on their respective target tissues and particularly the metabolic stimulation of NGF sensitive neurons by insulin lends strong support to the concept that insulin and NGF represent an example of distantly related proteins which have nevertheless retained a sufficient number of common structural features to allow them to perform related biological functions. Furthermore, the initial observations that insolubilized NGF, like insolubilized insulin, is biologically active indicate that the related function of these two proteins may well be expressed through a primary interaction with a receptor located on the surface membrane of the responsive cell.

POLYPEPTIDE MESSENGERS ARE AN integral part of the homeostatic control mechanisms of adult organisms. Unique among this class of molecules is nerve growth factor (NGF) which not only stabilizes the adult sympathetic nervous system, but also appears to direct its differentiation in the developing organism as well.[1] The wide species distribution of NGF, the specific cytotoxic effects of antiserum prepared against it[2] as well as the absolute requirement for NGF by

---

*Present Address: Laboratorio di Biologia Cellulare, CNR, Roma, Italia

sensory and sympathetic neurons *in vitro*,[1] all serve to establish the biological importance of this protein. NGF purified from male mouse submandibular glands[3] and several snake venoms[4,5] has been shown to cause the specific hypertrophy of sympathetic ganglia *in vivo* and to stimulate the anabolic metabolism of sympathetic neurons *in vitro*.[6,7]

Although the metabolic and morphological effects of NGF have been well documented, little is known about the mechanism by which these responses are elicited in its target cells. To provide the basis for experiments directed at this problem, detailed physical and chemical analyses of 2.5 S mouse submandibular gland NGF were undertaken. Ultracentrifugal analysis and quantitative end group determination revealed the 2.5 S molecule to be a dimer of very similar subunits.[8] Sequence analysis indicated that the primary subunit was composed of a 118 residue polypeptide chain of molecular weight 13,259 containing three intrachain disulfide bridges.[9,10] Side chain amide assignments[10] were consistent with the previously determined isoelectric point of 9.3.[11]

In addition to more clearly defining the molecular properties of NGF, the elucidation of the sequence provided the opportunity for comparing the primary structure of NGF with that of other proteins for the purpose of identifying proteins related to NGF by plausible evolutionary events. Initial comparisons with enzymes and proteins of similar size did not yield any significant homologies.[10] However, when NGF was aligned with several proteins of the hormone class, which displayed some similarities in biological function, apparently significant relatedness was observed with portions of NGF and insulin. Thus, the known sequences of various insulins and proinsulins were compared with that of NGF and the results of these more detailed comparisons of the primary and secondary structure as well as an examination of the biological function of insulin and NGF have led us to postulate that these two proteins are not only derived from a common evolutionary precursor but also remain functionally and mechanistically related in their present versions.[12]

Structural Comparisons

The comparison of insulin (proinsulin) and NGF at the primary structure level is summarized in Figure 1. The sequence of human proinsulin (PI)[13] and guinea pig insulin[14] are positioned with NGF[9,10] by alignment of the amino termini. Guinea pig insulin has been included in the alignment since it is the only other insulin sequence that supplies

a significant number of additional similar residues. This arrangement directly yields the maximum number of identities, enclosed with solid boxes, and favored replacements, enclosed with dashed boxes. Favored amino acid replacements are defined in this comparison from the relatedness-odds matrix[15] as interchanged amino acid pairs with a value R_{ij} greater than 10, where R_{ij} is ten times the ratio of the probability that the particular amino acid substitution occurred during the evolutionary development of two related proteins divided by the probability that the substitution occurred by chance. In this alignment, residues 1-81 of NGF correspond to residues 1-86 of human PI. In order to achieve maximum similarity, five deletions were inserted in the PI structure.

A numerical analysis of this comparison[12] indicated that significant structural similarity existed in the regions corresponding to the A and B chains but not the C peptide segment. The lack of similarity in this region is not so surprising since the C peptide is quite variable in sequence as well as length even among the five proinsulin sequences which have been elucidated.[13,16-18] Of more importance is the fact that the C peptides of human (or rat) PI fit into the alignment (Figure 1) without any deletions allowing the regions of NGF which are most similar to the two insulin chains to align perfectly with their corresponding identities in the insulin sequence.

An additional feature of this alignment of the insulin molecule with NGF that must be considered is the remaining 37 residues of NGF not accounted for by the proinsulin molecule. As depicted in Figure 1, the alignment of a second B chain (designated as B') satisfies this disparity, and as described below, allows for a plausible genetic explanation. It is noteworthy that the extent of similarity, as manifested by identical residues, is very limited in this region and the statistical data[12] suggest an only slightly higher than random relationship. This situation is improved somewhat if the four additional identities, obtained by examination of all known insulin sequences[14,15] are included in the comparison. These replacements make a total of 7 identical residues out of 32 (22%) in the B' segment as compared to 11 of 21 (52%) and 9 of 30 (30%) for the A and B chain segments, respectively. It should be pointed out that this nonuniform distribution of insulin identities within the NGF sequence may be of significance in delineating regions of functional importance in the NGF molecule.

The three peptide segments contained within the PI sequence have been shown to be arranged in the order B chain-C peptide-A chain.[16] Insulin is produced by proteolytic cleavage at each end of the C peptide leaving the A and B chains joined by two of the three insulin disulfide bridges. Thus the relation of the conserved regions to the disulfide structure in each molecule is an essential part of the comparison. These relationships are shown schematically in Figure 2. The consecutive line of circles represents the linear amino acid sequence of NGF and its relation to the corresponding residues of insulin is indicated by various degrees of shading. In order to emphasize the functionally important A and B chains of insulin, the NGF residues corresponding to these segments are indicated by solid circles and the C bridge and B' segments by broken circles. As can be seen by the distribution of the filled circles, which represent the identical residues in the region corresponding to the insulin A and B chains, and the cross-hatched circles, which represent the identical residues in the C bridge and B' segments, the highest concentration of identities occurs in the region corresponding to residues 6-15 and 68-80 of NGF.

Three of the identities of this group are half-cystinyl residues, two of which are bonded together in the same manner as the proinsulin disulfide bond which connects the B chain to the carboxyl region of the A chain (Cys B-19 to

Figure 1: The alignment of the amino acid sequence of mouse submandibular gland NGF[9,10] with those of human proinsulin[13] and guinea pig insulin.[14] Numbers above the sets of lines are those of the NGF residue positions and numbers below the sets of lines indicate the positions of the proinsulin and insulin residues. Solid boxes enclose sets of identical residues and dashed boxes enclose sets of residues considered to be favored amino acid replacements, defined as those pairs of residues with an R_{ij} value greater than the random value of 10.[15] Asterisks denote the positions at which residues from other insulins and proinsulins increase the number of identities and favored replacements. C-peptide

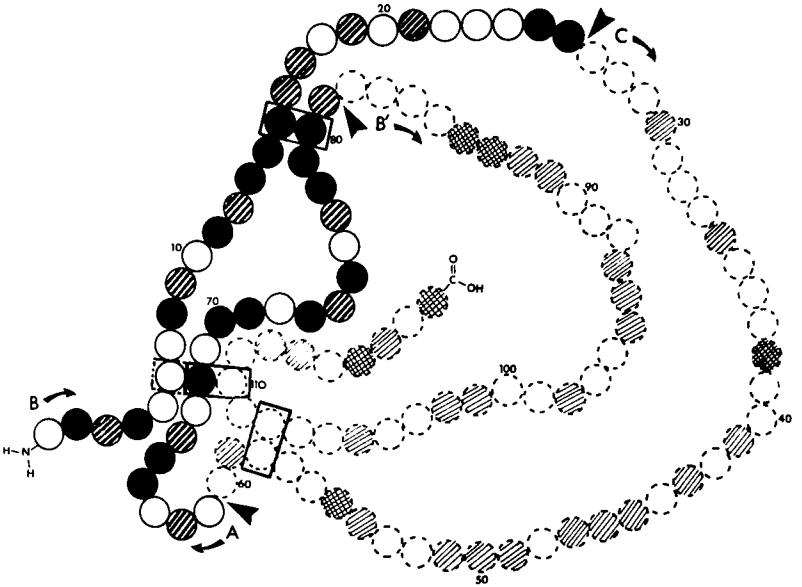

Figure 2: Schematic representation of the comparison of the covalent structure of human proinsulin and mouse 2.5 S nerve growth factor.[9,10] Solid circles indicate the portions of the NGF sequence which correspond to the functional B and A chains of insulin as indicated. (NGF 1-26 and NGF 61-81). Broken circles represent the segments of NGF which correspond to the insulin C-peptide and the repeated B chain, B'. Filled or cross-hatched circles indicate residues identical in both sequences. Diagonally shaded circles indicate favored amino acid replacements.[12] The deletions introduced into the NGF sequence (Figure 1) are not considered. The solid boxes enclose pairs of half-cystinyl residues which form disulfide bonds in NGF. The dotted extension of the box enclosing residues 68 and 110 in NGF indicates the corresponding disulfide bridge in human proinsulin. Arrowheads mark the peptide bonds for NGF which correspond to the cleavage points for the activation of proinsulin.

Cys A-20).[19] The third conserved half-cystinyl residue is not bonded in the same manner in the two molecules. This residue, Cys 80, is linked to Cys 110 in NGF, as indicated by the solid box, while in insulin it is bonded to the residue corresponding to residue 6 of NGF (see Figure 1) as indicated by the dashed box. Thus, the partially conserved disulfide pairing strengthens the proposed relationship of the two proteins and indicates that some of the regions of NGF and insulin will have similar three-dimensional structures while other portions, particularly in the areas where the disulfide bonding is different, are probably quite dissimilar. The similarities and differences in biological action may be reflected in the same way as these structural features.

Evolution of Nerve Growth Factor

The similarities in primary and secondary structure of NGF described above suggest a structural and evolutionary relationship to proinsulin. Although the observed similarity is greatest with the functionally significant A and B chains, the portion of NGF corresponding to the repeated B chain is clearly suggestive of a gene duplication event. Two possible evolutionary routes, involving such steps and leading to the production of mouse NGF from an ancestral proinsulin-like molecule, are depicted in Figure 3. Both pathways invoke a duplication of the ancestral gene resulting in two independent genes in the manner now classical for proteins related by primary structure.[20] One gene would then have undergone a further duplication (contiguous reduplication, Figure 3) to produce a gene twice the length of the original, coding for a protein of some 170 amino acid residues, while the other evolved into proinsulin. Analogous events have been described for the human haptoglobins[21] and for the immunoglobulins.[22] From this point, two possible routes diverge. The first possibility would involve the deletion of the genetic material coding for the carboxyl-terminal C peptide and A chain regions of the double proinsulin-like peptide, so that a protein of some 120 residues would be produced. The second alternative would involve no further genetic events materially affecting the length of the gene, so that the primary gene product would thus be some 170 residues long. After translation, a proteolytic event (or events) would cleave this larger NGF molecule to yield 2.5 S NGF (118 residues), containing the regions corresponding to the first complete PI molecule plus the B' chain, and the carboxyl-terminal segment (*ca.*

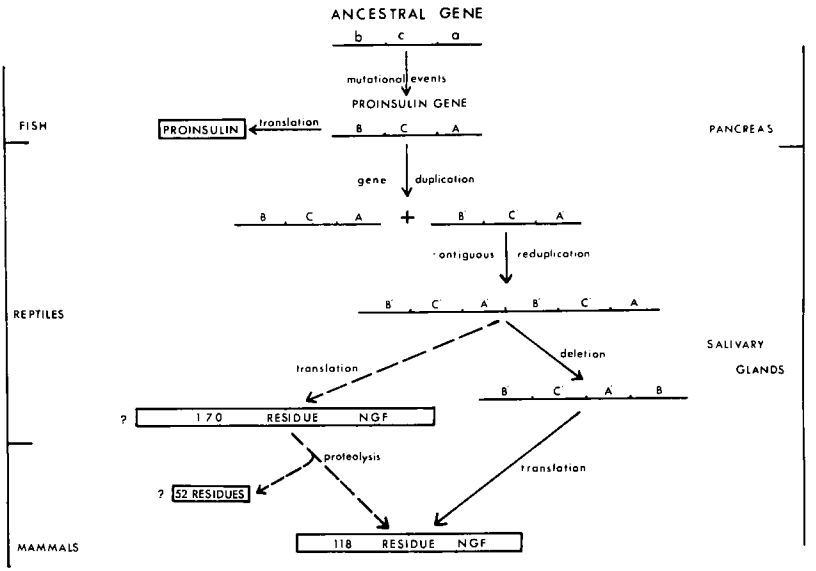

Figure 3: A hypothetical scheme depicting the evolution of NGF in its present form (118 residues) from an ancestral proinsulin-like molecule by a series of plausible genetic events. Bars indicate genes, the modes dividing them into regions corresponding to the peptide regions of proinsulin. Boxes represent gene products (proteins) and the dotted arrows indicate a hypothetical pathway (see text). The scale on the left indicates an evolutionary era during which the most highly developed animal extent was that named between the dividing marks and during which the events depicted in the central part of the figure are presumed to have occurred. The right hand scale is comparable in time to that on the left, but the organ has been listed in which the translational events depicted in the central figure occur. Taken in part from reference 12. (Copyright 1972 by the American Association for the Advancement of Science).

52 residues) containing regions corresponding to the C' peptide and A' chain.

While definitive evidence favoring one of these two pathways is lacking, several considerations tend to support limited proteolysis. For example, the carboxyl-terminal residue of NGF is arginine. NGF is usually isolated from the submandibular gland as part of a multiprotein complex, as described by Varon *et al.*,[23] which contains as one of its subunits a potent arginine esterase. Such an enzyme could perform the required cleavage of the larger NGF molecule at the carboxyl-terminus to produce the shortened form. Furthermore, this carboxyl-terminal arginine corresponds to one of the sites at which proinsulin is cleaved. A similar possibility based on the same structural feature has been suggested for epidermal growth factor by Taylor *et al.*[24] which is also isolated from mouse submandibular glands.

It is interesting to note that the residues of NGF which align with the two cleavage points of the first PI molecule (NGF 27, 28 and NGF 60, 61) are not the argininyl bonds which are cleaved in PI to produce insulin. This observation raises the question as to whether they have subsequently appeared in proinsulin or disappeared in NGF. Although this question is not readily resolvable, it seems probable that insulin has evolved directly as the zymogen. This molecule probably originally possessed full activity, which has been passed on, albeit in somewhat altered form, to NGF which still exerts its physiological effects without requirement for cleavage within the part of the NGF molecule that corresponds to proinsulin. It is a direct consequence of this hypothesis that the proinsulin precursor gene must have acquired inactivity by mutation which has been subsequently counteracted at the phenotypic level by proteolytic activation.

The evolutionary development of the organs of origin of these two proteins is also indicated in Figure 3. Interestingly, the salivary glands of vertebrates parallel the appearance of NGF while insulin and the pancreas appeared significantly earlier, being found even in primitive fish. Salivary glands of the vertebrate type are first found in amphibians.[25]

The more extensive sequence data available for insulins of different species[14,15] allows some reconstruction of the genetic events marking the pathways illustrated in Figure 3. These data indicate that insulins can be subdivided into two classes--fish and mammalian. The higher degree of similarity of mouse NGF with the mammalian insulins suggests

that the first gene duplication event (Figure 3) occurred after the divergence of fish and higher vertebrates. There is, however, insufficient information, particularly with regard to the structure of other NGF molecules to allow any more detailed conclusions.

Physical Chemical Comparisons

It has been well established that proteins of the same class, *e.g.* the serine proteases, which display sequential similarity, including conservation of the intrachain disulfide crosslinks, possess high degrees of similarity in the course of folding of the main polypeptide chains.[26] In the absence of crystallographic analyses, three-dimensional comparisons must be conducted at less specific levels by examination of various physical and chemical properties. One such property which is known to depend on the three-dimensional arrangement of amino acid residues is the solution aggregation behavior of proteins. Insulin, proinsulin and NGF all exist as specific dimers or higher even aggregates over a wide range of pH.[8,27-29] A unique property of insulin and proinsulin is the polymerization to hexamers induced by zinc which depends on the histidine at position 10 of the insulin B chain.[30] Since this histidine is conserved as His-8 in the NGF sequence, it may be possible for NGF to polymerize in the presence of zinc. Experiments in progress to test this hypothesis have been complicated by the presence of chains missing the first eight residues (and hence, His-8) in some preparations of NGF.[9,10]

Two parameters which also reflect the polypeptide chain conformation are the optical rotatory dispersion (ORD) and circular dichroism (CD) spectra of proteins. Frank and Veros[28] have reported ORD and CD spectra for insulin and proinsulin at neutral pH, and concluded that the spectra are representative of approximately 25% α-helical structure in insulin and 14% α-helix in proinsulin. They concluded that the lower percentage in proinsulin is due to the additional residues of the C peptide in an "unordered" or "random" conformation (Table I). The percentage α-helix in the insulin structure is borne out by the model deduced from crystallographic studies.[30,31] The ORD and CD spectra of NGF at pH 5 and pH 8.5 indicate that the molecule consists of approximately equal proportions of unordered and β structure with a low (*ca.* 7%) α-helix content.[32] Thus, the number of residues in the α-helical conformation is approximately the same in insulin, proinsulin and NGF, the

Table I

The Relative Helicity of Insulin, Proinsulin and Nerve Growth Factor as Derived from Circular Dichroic Spectra

[b] Per cent α-helix calculated for NGF using the depth of the trough at 208 nm.[32]

remainder of each being composed of unordered and β structure (Table I). Particularly in the case of NGF, this conclusion is supported by the large number (45%) of helix destabilizing residues[33] in the sequence. The conformation of NGF as revealed by ORD and CD measurements is thus consistent with the possibility that some regions of the three-dimensional structure of NGF may parallel portions of proinsulin or insulin. Conclusive proof of this hypothesis, however, must await the collection of high resolution structural data for both proinsulin and NGF.

Functional Similarities and Mechanistic Implications

The conservation of specialized function through large spans of evolution is a well documented concept. Thus, while a structural comparison of NGF and insulin has shown them to be distantly related, a consideration of the functional properties of the two proteins indicates close similarities in their effects on their respective target tissues. For example, the spectrum of stimulatory anabolic effects of insulin on 3T3 cells *in vitro*, referred to as the "positive pleiotypic response,"[34] exactly parallels the metabolic response of sensitive neurons to NGF. A process that is in some ways distinct from the metabolic stimulation is nerve fiber outgrowth. This morphological "end point" of the *in vitro* NGF response, occurs in the presence of actinomycin D [7](but not *p*-fluorophenylalanine[6] or cycloheximide[7]) and may thus represent post-transcriptional control of protein synthesis.[7] Insulin has been shown to act at a post-transcriptional stage in the case of tyrosine amino transferase induction in rat hepatoma cells.[35] Just as protein hormones amplify tissue-specific processes, NGF has recently been shown to increase the activity of enzymes specific for noradrenergic function, including tyrosine hydroxylase and dopamine-β-hydroxylase.[36]

Particularly interesting with regard to the functional similarity of insulin and NGF is the fact that insulin can stimulate the anabolic metabolism of NGF-sensitive sympathetic neurons.[37,38] While many agents are capable of producing a growth response in various cell types, this observed physiological "cross-reaction" of insulin with NGF sensitive nerve tissue strongly suggests that the structural similarities noted for these two proteins reflect the conservation of related function at the level of cellular response.

As in the case of NGF, little is known about the initial biochemical events which trigger the insulin response in

its target tissues. However, Cuatrecasas has used insoluble derivatives of insulin coupled covalently to Sepharose to demonstrate that insulin acts at the surface membrane of responsive cells.[39] Furthermore, all of the insulin binding activity of fat and liver cells resides in the plasma membrane fraction of cell homogenates[40] from which a protein retaining insulin binding activity has been purified.[41,42]

To explore the possibility that NGF may also act at the cell membrane of responsive neurons, insoluble derivatives of NGF were prepared by reacting NGF at pH 6.4 with cyanogen bromide-activated Sepharose. This procedure (essentially that of Cuatrecasas[43]) produces a highly substituted derivative containing 2 mg (0.15 μmoles) of NGF per ml of packed Sepharose beads. After extensive washing, 5 ml of NGF Sepharose was washed with one liter of water which was then lyophilized and redissolved in 1 ml; no NGF activity could be detected in this wash with the biological assay which is sensitive to less than 20 nanograms of NGF per ml.

Since native 2.5 S NGF is a tightly associated dimer,[8] the possibility existed that only one subunit of the dimer might be covalently linked to the Sepharose allowing the other subunit to dissociate during the prolonged incubations. To eliminate this possibility, NGF-Sepharose was incubated in 6 *M* guanidine hydrochloride, pH 5, for 24 hr at 37° followed by further washing with 6 *M* guanidine hydrochloride and finally with buffer. This treatment resulted in the release of very little NGF from the resin indicating that most of the molecules were bound covalently through each subunit of the dimer. The guanidine HCl treatment ensures that no noncovalently bound NGF remains in the NGF-Sepharose preparation.

The insoluble NGF-Sepharose derivatives prepared in this manner were tested for biological activity. One of the most reliable indications of NGF activity is the stimulation of nerve fiber outgrowth from primary explants of eight day chick embryo dorsal root ganglia. These ganglia explants were cultured in liquid medium and in plasma clot preparations with NGF-Sepharose and control Sepharose. Since the ganglia are only about ten times the size of a Sepharose bead (~600μ *vs* ~60μ), the number of beads that can pack around a ganglion is quite limited, and only a few cells at the surface of each ganglion can be stimulated. Thus in these experiments, which depend on the morphological response, one cannot expect to observe neurite outgrowth of the type stimulated by soluble NGF in which all responsive cells contribute to the fiber outgrowth. Nevertheless, when ganglia explants are cultured with NGF-Sepharose for

24-48 hours, tufts of nerve fibers can be seen originating at points on the surface of the ganglia which are in close contact with Sepharose beads. Longer term cultures maintained up to ten days in the presence of NGF-Sepharose exhibit large numbers of surviving neurons which appear in clumps covered with Sepharose beads. Nerve fibers, many several millimeters long, form a network of thick bundles which span the entire distance between the groups of neurons which remain at the position at which the ganglia were originally placed. Figure 4 shows a part of such a culture maintained 9 days with NGF-Sepharose.

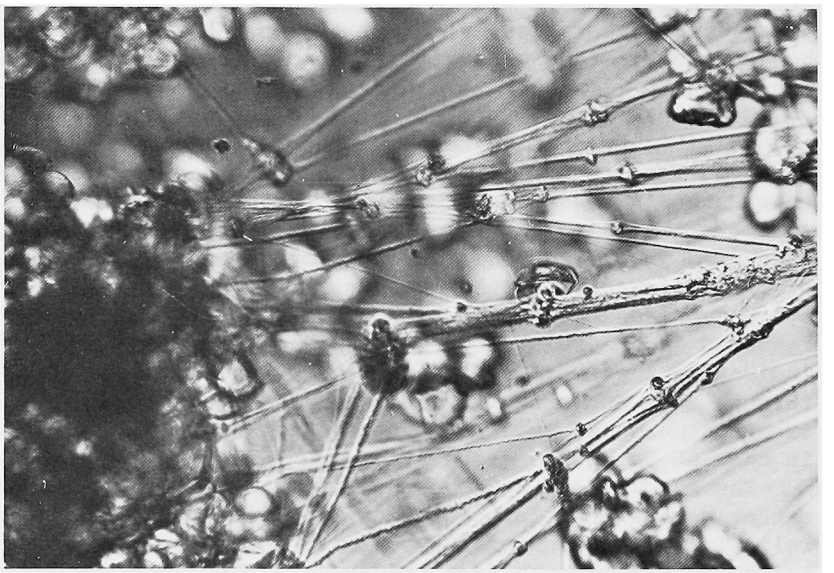

Figure 4: The effect of NGF-Sepharose on 8-day old chick embryo dorsal root ganglia after long term culture (9 days). Bundles of nerve fibers can be seen to connect two sensory ganglia. The dark mass in the lower left is a dorsal root ganglion covered with Sepharose beads. The Sepharose beads clinging to the surface of a second ganglion are seen in the upper right. The distance between the two ganglia is approximately 1 mm. Additional nerve fibers which lie in other focal planes can also be seen. Control ganglia incubated with untreated Sepharose showed no fiber outgrowth over the same period (Nomarski Optics, *ca.* 150X).

Control explants cultured in the presence of untreated Sepharose show no fiber outgrowth during any stage of culture. In these experiments, the Sepharose beads do not adhere to the ganglia and after a few days only fibroblastic and other nonneuronal cell types survive, distributed randomly throughout the culture.

These observations are consistent with the hypothesis that NGF exerts its action through interaction with the cell membrane of responsive neurons. Furthermore, the NGF response noted in these cultures was not due to dissociation from the Sepharose of non-covalently bound NGF since the results were the same whether the NGF-Sepharose had been treated with guanidine HCl or only washed with large volumes of buffers. There remain, however, other means by which soluble NGF activity could be generated from the Sepharose derivative. These include the release of enzymes by the cells in culture which could degrade the Sepharose to yield NGF attached to a few sugar residues or enzymes that could proteolyze the insoluble NGF to produce active fragments. These possibilities are unlikely since no gross degradation of the Sepharose was noted even in long term cultures, and experiments to generate active fragments of NGF with known proteolytic enzymes have thus far yielded no active peptides. Experiments to more rigorously eliminate the generation of soluble NGF activity from the insolubilized derivatives are presently in progress.

While the similarities in the metabolic function of NGF and insulin described above tend to support the structural relationship observed for the two proteins, these common effects can be considered little more than coincidental in the absence of information about the means by which these actions are initiated. The experiments with insolubilized NGF supply this type of information and indicate that, like insulin, the primary action of NGF is its interaction with the cell membrane. Thus the observed functional similarities between insulin and NGF may well be manifested through a common primary mechanism and as such may indeed reflect the persistence through divergent evolution of common structural features.

CHEMISTRY AND BIOLOGY OF PEPTIDES

SIGNIFICANCE AND INTERACTION OF THE AMINO ACID RESIDUES IN POSITIONS 1, 2, 3 AND 8 OF VASOPRESSINS ON CONTRACTILE ACTIVITY IN VASCULAR SMOOTH MUSCLE

Burton M. Altura. Departments of Anesthesiology and Physiology, Albert Einstein College of Medicine of Yeshiva University, Bronx, New York

UNTIL RECENTLY, VASOPRESSIN WAS given little serious thought as a useful vasoactive drug because of its well documented coronary constrictor action. However, evidence has now accumulated to suggest that at least two synthetic analogues of vasopressin namely [2-phenylalanine, 8-lysine]-vasopressin (PLV-2) and [8-ornithine]-vasopressin, may have significant antiarrhythmic properties.[1,2] Furthermore, PLV-2 has been reported to increase the relative myocardial blood flow in rats[3] and to relax a variety of isolated bovine coronary arteries.[4] Possibly more importantly, PLV-2 has been reported to be very beneficial in the treatment of various forms of experimental and clinical shock syndromes.[5-9] The anti-shock action of PLV-2 is thought to be due to its unusual microcirculatory actions.[6,7,9-12] Interestingly, several synthetic analogues of vasopressin, including PLV-2, have been shown, by direct *in vivo* microscopy, to have a predominant constrictor (or contractile) action on muscular venules in the microcirculation; *i.e.*, changes in the molecular structure of [8-arginine]--or [8-lysine]--vasopressin in positions 2, 3 and 8 can change the affinities of the altered peptide for a particular type of peripheral microscopic blood vessel (*e.g.*, arteriole, venule, metarteriole, precapillary sphincter).[9-12] In view of such surprising findings we initiated systematic pharmacologic and structure-activity studies of the neurohypophyseal hormones (NHPH), and their synthetic analogues, not only

at the microcirculatory level[9-12] but on various types of isolated mammalian blood vessels[4,12-15] since the latter would be divorced from any *in vivo* effects of metabolism and blood flow; factors which could compromise rat pressor assays.

It is generally believed that the degree of basicity of the amino acid residue in position 8 of vasopressin is probably the single critical structural factor for optimizing the pressor or vasoconstrictor properties of the molecules.[16,17] This hypothesis is, however, primarily based on crude intravenous blood pressure assays in adrenergically blocked rats. But such *in vivo* assays may not give accurate estimates of either the potencies or affinities* of these peptide molecules on vascular smooth muscle.[10-13,15,18] For example, we recently presented data on a variety of isolated canine blood vessels[12-14] which suggest that: (a) the *length* of the amino acid side chain interacting with the basicity in position 8 of the vasopressins may be extremely important for both affinity and intrinsic (contractile) activity* of these peptides on vascular smooth muscle; (b) the phenolic and aromatic groups in positions 2 and 3, respectively, of the vasopressins may also be of importance not only for affinity but intrinsic contractile activity as well; (c) there might be chemical or steric differences from one target site to another within the receptor molecules in different blood vessels, even within a single mammalian species; and (d) different isolated canine blood vessels from different regional vascular beds appear to exhibit different dependencies on magnesium ions for [8-arginine]-vasopressin-induced contractions.[14]

Since our previous studies were done on isolated canine blood vessels and most all of the structure-activity data derived so far for the NHPH has been projected on the basis of rat pressor assays, several possibilities could be entertained to explain the discrepancies between our data and that of others: (1) species differences, (2) *in vitro versus in vivo*, (3) arterial *vs.* arteriolar responsiveness (*i.e.*, heterogeneity of drug receptors which subserve contraction may exist with respect to the structure-activity relationships of the NHPH and analogues on blood vessels [11-15,20]), (4) not enough analogues were examined in our *in vitro* studies, and (5) complex autonomic reflex actions may complicate rat pressor assays.[18] The present study using

*For a thorough discussion of affinity and intrinsic activity see reference 19.

12 NHPH peptide analogues and direct *in vivo* microscopy on rat mesenteric arterioles and isolated rat aortas was therefore designed to elucidate these contingencies. Delineation of structure-activity correlations are strategic requirements for the design of new NHPH with more precise vasomotor selectivity, especially in view of the therapeutic potential of such molecules in the treatment of low-flow states.[5-9]

Isolated, helically cut thoracic rat aortic strips were set up for isometric recording as described previously.[21] The rat mesocecal mesenteric preparation[10] was used for the direct *in vivo* study of arterioles. *In vivo* quantitative microscopic observations were carried out on rat mesenteric arterioles by means of an image-splitting television microscope recording system.[22] The latter TV system, at magnifications up to 4,000 times, allowed us to quantitatively make rapid measurements of lumen diameters in response to topical application of 0.1 ml volumes of the neurohypophyseal peptides. Such a system has very recently been effectively used to make rapid *in vivo* micrometric measurements from which complete log dose-response curves have been constructed for drug effects on various kinds of muscular microvessels including arterioles.[23-25]

The present *in vitro* and *in vivo* findings on rat arterial and arteriolar smooth muscle (Figures 1 and 2) suggest that

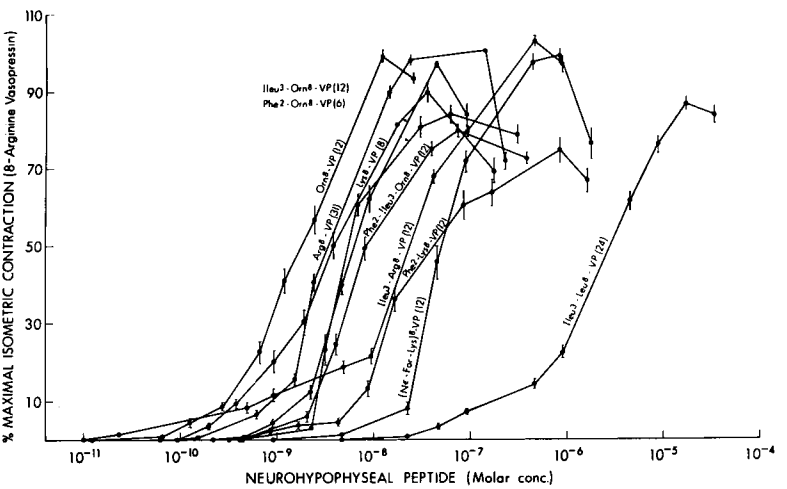

Figure 1: Comparative contractile actions of neurohypophyseal hormones and synthetic analogues on isolated rat aortas. Numbers in parentheses denote the number of different male rats utilized. Values are means ±S.E.M. Cumulative log dose-isometric response curves.

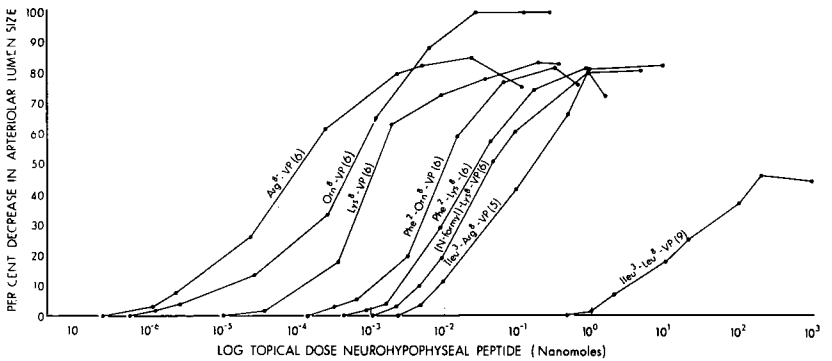

Figure 2: Graded contractile responses of rat mesenteric arterioles to topically applied neurohypophyseal hormones and synthetic analogues. Note that the abscissa is expressed in nanomoles. Each point represents the mean value ± S.E.M. obtained from *in vivo* measurements on vessels from different male rats (indicated by numbers in parentheses). The mean control lumen sizes for the arterioles range from 22 to 30μ.

an optimum interaction between the length of side chain and basicity in position 8 is, indeed, necessary for maximal activation (or contraction) of smooth muscle cells by the vasopressin receptor in mammalian somatic vascular muscle.[12,13] Maximal basicity alone in position 8 does not in itself promote optimum contractile activity (*e.g.*, [8-ornithine]-vasopressin is more potent than either [8-arginine]--or [8-lysine]--vasopressin). Furthermore, the present data on rat blood vessels support our previous suggestion that the phenolic and aromatic groups in positions 2 and 3, respectively, are involved in both the affinity and the intrinsic activity of the hormone on vascular muscle.[12,13] Analogues lacking either of these functional groups (*e.g.*, [2-phenylalanine, 8-lysine]-vasopressin, [3-isoleucine, 8-ornithine]-vasopressin, [3-isoleucine, 8-arginine]-vasopressin) have reduced affinity and intrinsic activity (Figures 1 and 2).

The absence of only the functional amino group also results in a marked loss of both affinity and intrinsic activity (Figure 3). This is, thus, quite different from

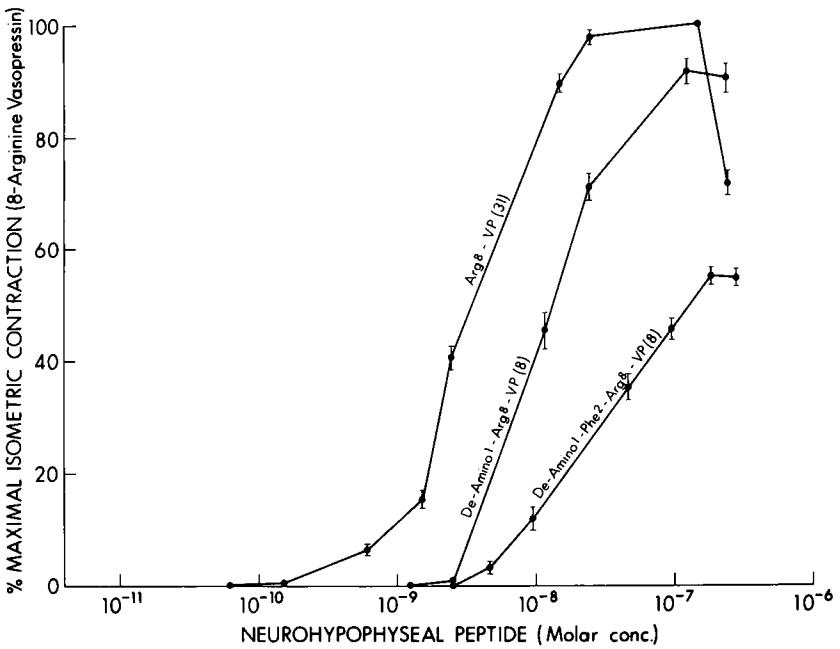

Figure 3: Comparative contractile actions of [8-arginine]-vasopressin, deamino-[8-arginine]-vasopressin and deamino-[2-phenylalanine, 8-arginine]-vasopressin on isolated rat aorta.

that which has been reported for this functional group in oxytocin on uterine smooth muscle.[26] Simultaneous absence of both the functional amino group and the phenolic hydroxyl (*e.g.*, 1-deamino-[2-phenylalanine, 8-arginine]-vasopressin) results in further losses in both affinity and intrinsic activity of the hormone on rat blood vessels (Figure 3). Thus the amino group in position 1, the phenolic hydroxyl in position 2 and the aromatic group in position 3 all are required to promote optimum hormonal contractile activity on mammalian somatic blood vessels.

The widely divergent relative affinities and intrinsic activities seen for a variety of NHPH analogues on rat aorta *versus* rat arterioles could not only be used to support our previous suggestion that the vasopressin receptor may not be identical on blood vessels within a single mammalian species,[12-14] but could aid in explaining some or all of the discrepancies observed between our observations and crude rat pressor assays. These present data when coupled with previous observations[4,10-15,23,25] emphasize the importance of a comparative pharmacologic approach in the analysis of structure-activity relationships for NHPH in the cardiovascular system and could be used to buttress the concept that drug molecules with *selective regional vascular actions* can be realized.

Acknowledgments

This study was supported by research grants HL-12462 and HL-11391 from the National Institutes of Health, USPHS. I thank Mr. C. F. Reich and Mr. R. W. Burton for their excellent technical assistance. I am deeply indebted to Dr. B. Berde, Sandoz Ltd., and Dr. R. Walter, Mt. Sinai School of Medicine, for generously supplying the pure, synthetic peptides used in these studies. Burton M. Altura, recipient of Research Career Development Award 5-K3-GM-38, 603 from the N.I.H., USPHS.

DIRECTED BIOSYNTHESIS OF ANTIBIOTIC PEPTIDES WITH ISOLEUCINE STEREOISOMERS AND DL-PIPECOLIC ACID

Edward Katz, Joseph V. Formica, Takehiko Yajima, Mary Ann Grigg.* Department of Microbiology, Georgetown University Schools of Medicine and Dentistry, Washington, D.C.

STREPTOMYCES CHRYSOMALLUS produces a number of actinomycins which contain D-valine, D-alloisoleucine or both amino acids, whereas those synthesized by *S. antibioticus* contain D-valine (Figure 1).[1] *N*-Methyl-L-valine is also a normal constituent of the actinomycins. We have carried out studies to determine the effect of the four stereoisomers of isoleucine on actinomycin peptide formation.

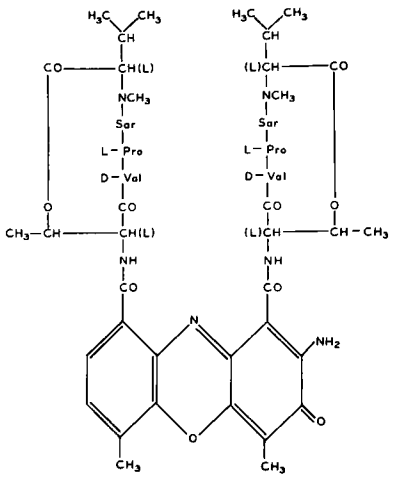

Figure 1: The structure of actinomycin D.

*Present Address: Department of Microbiology, Medical College of Virginia, Richmond, Virginia.

The influence of various concentrations of each of the four stereoisomers of isoleucine on the production of actinomycin mixtures by *S. antibioticus* was examined. D-Alloisoleucine and D-isoleucine were found to be quite inhibitory to antibiotic formation, whereas little effect was observed with L-isoleucine and L-alloisoleucine. The latter compound did inhibit antibiotic production, to some extent, for a 24-hour period.

Amino acid hydrolysates of actinomycin mixtures were examined by high voltage electrophoresis (4% formate, 4800 V, 3 hr) in one dimension, followed by paper chromatography (butanol-acetic acid-water, 4:1:5) in the second dimension. By this procedure, it was ascertained that isoleucine and *N*-methylalloisoleucine (but not *N*-methylisoleucine) were present in actinomycin preparations synthesized in the presence of L- or D-isoleucine or L-alloisoleucine. Quantitative data of amino acids in actinomycin hydrolysates (*S. antibioticus*) were obtained with the Beckman Model 120 C amino acid analyzer. Control mixtures contained *N*-methyl-valine predominantly; but, in addition, small amounts of *N*-methylalloisoleucine were found. D-Valine also predominates, but trace amounts of isoleucine, alloisoleucine and even leucine were detected. Significant levels of *N*-methylalloisoleucine, isoleucine and even alloisoleucine were found with each of the four isomers of isoleucine supplied in the medium. Similar results were obtained in experiments with *S. chrysomallus*.

Isoleucine and *N*-methylalloisoleucine were isolated and purified from hydrolysates of the actinomycin mixture formed in the presence of D-isoleucine by *S. antibioticus*. Homogeneity and identity of the amino acids were established with standard amino acids by high voltage electrophoresis, paper and column chromatography.

Optical configuration of the amino acids was determined by optical rotatory dispersion.[2] *N*-Methyl-L-alloisoleucine exhibited a positive Cotton effect; by contrast, isoleucine showed a negative Cotton effect denoting that the isoleucine has the D-configuration. L-Leucyl dipeptides were prepared with the four stereoisomers of isoleucine and with the isoleucine isolated from actinomycin mixtures by the method of Manning and Moore.[3] It was established that the dipeptide synthesized with the isoleucine isolated from actinomycin hydrolysates had the same retention time as the standard of L-leucyl-D-isoleucine. Isoleucine purified from hydrolysates also was incubated with dialyzed preparations of L- or D-amino acid oxidase. The amino acid was destroyed after D-amino acid oxidase, but not after L-amino acid oxidase treatment, providing further evidence that isoleucine has the D-configuration.

The mechanism of biosynthesis of D-isoleucine and *N*-methyl-L-alloisoleucine from the various stereoisomers of isoleucine remains to be established with cell-free systems. The interconversion of the four stereoisomers probably involves both enzymatic and non-enzymatic reactions with the keto acids (L-α-keto- and D-α-keto-β-methylvaleric acid) playing a key role in the process.[4] Presumably, the enzymatic methylation of the appropriate L-amino acid (*e.g.*, L-valine normally or L-alloisoleucine) involving S-adenosylmethionine leads to *N*-methylamino acid synthesis. Based on recent studies concerning the ATP-dependent racemization of L-phenylalanine to D-phenylalanine during gramicidin S and tyrocidine formation by *Bacillus brevis*,[5,6] it is postulated that a single racemase with rather broad specificities for the L-form of the branched chain amino acids catalyzes an energy-dependent biosynthesis of the D-amino acids, D-valine, D-alloisoleucine and D-isoleucine. The data reveal that *N*-methyl-L-alloisoleucine and D-isoleucine substitute for *N*-methyl-L-valine and D-valine, respectively, in actinomycin peptides.

The actinomycins synthesized by *S. antibioticus* differ solely in the imino acid site of the antibiotic molecule.[1] When DL-pipecolic acid, the higher analogue of proline, was supplied during antibiotic formation, several new actinomycins were synthesized by *S. antibioticus*.[7] These antibiotics, isolated and purified from mixtures, were designated actinomycins Pip 2, Pip 1 alpha, Pip 1 beta, Pip 1 gamma, Pip 1 delta and Pip 1 epsilon. The amino acid composition of the various actinomycins was established qualitatively by a combination of high voltage electrophoresis and paper chromatography. Quantitative data reveal that the new actinomycins contain two residues each of D-valine, *N*-methyl-L-valine, sarcosine and L-threonine, but differ in the number of the imino acid residues (Pip 2: pipecolic acid - 2; Pip 1 beta: proline - 1, pipecolic acid - 1; Pip 1 alpha: pipecolic acid - 1, 4-oxopipecolic acid - 1; Pip 1 delta: proline - 1, 4-oxopipecolic acid - 1; Pip 1 gamma: pipecolic acid - 1, 4-hydroxypipecolic acid - 1; Pip 1 epsilon: proline - 1, 4-hydroxypipecolic acid - 1).

The presence of pipecolic acid and 4-oxopipecolic acid was confirmed by cochromatography and coelectrophoresis with authentic standards of these amino acids. Also, a comparison of hydrolysates of actinomycins Pip 1 alpha and Pip 1 delta with hydrolysates of Vernamycin B alpha and Ostreogrycin, peptide antibiotics known to contain 4-oxopipecolic acid, revealed the presence of the oxoimino acid in the actinomycin components. Further, oxopipecolic acid was reduced with sodium borohydride to a mixture of *cis*-4-hydroxypipecolic

acid and *trans*-4-hydroxypipecolic acid as reported by Clark-Lewis and Mortimer.[8] The identity of the imino acid in actinomycins Pip 1 gamma and Pip 1 epsilon as *trans*-4-hydroxypipecolic acid was established also by cochromatography and coelectrophoresis with authentic *cis*- and *trans*-4-hydroxypipecolic acid and with 3- and 5-hydroxypipecolic acid.

The effect of the six pipecolic acid-containing actinomycins on the *E. coli* DNA-dependent RNA polymerase reaction was also studied. The data correlate well in that actinomycins containing at least one proline residue were found to be more inhibitory than those containing a pipecolic acid residue in place of proline. Moreover, the actinomycins that contain hydroxypipecolic acid (Pip 1 epsilon, Pip 1 gamma) exhibited the lowest activity for each series of compounds. The order of activity: actinomycin IV = Pip 1β > Pip 1 delta > Pip 1 epsilon > Pip 2 > Pip 1 alpha > Pip 1 gamma.

Normally, *S. antibioticus* synthesizes proline from glutamic acid during actinomycin production.[1] Proline is incorporated directly into actinomycin peptides or is modified via hydroxylation or oxidation reactions to give *trans*-4-hydroxy-L-proline (actinomycin I) or 4-oxo-L-proline (actinomycin V), respectively.[9,10] When supplied with the proline analogue, pipecolic acid, the organism apparently catalyzes similar types of biochemical reactions. The utilization of these compounds results in the synthesis of novel actinomycins with quantitatively differing biological properties.

CHEMISTRY AND BIOLOGY OF PEPTIDES

MECHANISM OF THROMBIN ACTION ON FIBRINOGEN; ACTIVITY OF THROMBIN TOWARD HUMAN α(A)-FIBRINOGEN PEPTIDES

L. C. Dorman, R. C. Cheng, F. N. Marshall. Chemical Biology Research, The Dow Chemical Company, Midland, Michigan 48640

ONE OF THE KEY EVENTS involved in the clotting of blood is the reaction of thrombin on fibrinogen.[1] Thrombin cleaves the Arg-Gly bonds in the α(A) and β(B) chains of fibrinogen releasing peptides A and B. Subsequently, the α and β chains of the remaining protein, fibrin, are crosslinked covalently by fibrin stabilizing factor forming a permanent clot.

As far as proteins are concerned, the action of thrombin is bond and protein specific, *i.e.*, only the Arg-Gly bonds in the protein fibrinogen are cleaved by thrombin. Many studies of this reaction indicate that the high specificity of the reaction is not associated with the conformation of fibrinogen. Instead the primary structure or amino acid sequence around the Arg-Gly bonds have become suspect as being responsible for this high specificity.[2] Shortly after the 50-unit N-terminal sequence of the α(A) chain of human fibrinogen was reported,[3] we initiated a study to test this hypothesis.

Nonapeptide, H-Gly-Val-Arg-Gly-Pro-Arg-Val-Val-Glu-OH (*1*), the 14-22 sequence of human α(A) fibrinogen was synthesized by the solid-phase method.[4] When a 0.2% solution of *1* was digested with thrombin (48 NIH units/ml)[5] and soybean trypsin inhibitor (0.04% solution)[6] in 0.15*M* NH_4HCO_3, pH 8.2, at 37° for 4 hr, a rather complex cleavage pattern was observed involving both Arg-Gly and Arg-Val peptide bonds (Scheme I). Cleavage products were isolated by ion-exchange and gel chromatography and identified by amino

Scheme I

acid analyses and by comparison of their tlc and tle mobilities with authentic peptides.

Having demonstrated that *1* was a thrombin substrate, reactivity towards analogs of *1*, *i.e.*, *7-11*, was examined to determine the effects of structural change (cf. Table I).

With regard to Arg-Gly cleavage, substitution of Pro^{18} by Gly had little effect. Blombäck[3] had speculated that this proline residue aids in exposing Arg-Gly of the α(A) chain of fibrinogen to thrombin attack. Substitution of Arg^{19} by Gly reduced the extent of Arg-Gly cleavage. The [Sar^{17}] analog (*9*) was relatively stable to thrombin attack as was *10* in which adjacent Gly^{17} and Pro^{18} were reversed. Shortening of peptide *1* at the C-terminus, *i.e.*, *11* had no apparent effect on Arg-Gly cleavage. There was apparent greater specificity toward Arg-Val cleavage; Val-Val-Glu was readily formed from *1*, but very little or none was detected in the reactions of *7*, *9* and *10*. Thrombin cleavage of Arg-Val has been observed on large (43 and 50 residues) N-terminal fragments of the α(A) chain,[7,8] but the rate was reported[7] to be considerably slower than Arg-Gly cleavage.

Table I

O=very little or no reaction

To assess the relative potential of these peptides and their fragments to bind thrombin, "thrombin times," *i.e.*, inhibition of thrombin to clot fibrinogen, were determined. Generally, thrombin times were not significantly above controls except for fragment[8] Gly-Pro-Arg (*4*), which was higher than that of Tos-Arg-OMe (TAME), the standard thrombin substrate. The high binding of *4* to thrombin prompted us to look at some of its analogs and derivatives, *12-18*, presented in Table II with clotting data. These data show that amino or carboxyl protection of Gly-Pro-Arg diminishes thrombing binding. More significantly, a smaller protected peptide, Boc-Pro-Arg-OBzl (*17*) displayed even higher thrombin binding.

CHEMISTRY AND BIOLOGY OF PEPTIDES

STUDIES ON BRADYKININ-POTENTIATING PEPTIDES

Duane A. Tewksbury. Marshfield Clinic Foundation for Medical Research and Education, Marshfield, Wisconsin.

BRADYKININ-POTENTIATING PEPTIDES have been isolated from snake venoms.[1,2,3] Peptides with this activity have also been obtained from the plasmin hydrolysis of fibrinogen and fibrin,[4] from the trypsin hydrolysis of plasma[5,6] and from the trypsin hydrolysis of albumin.[6] This paper reports the study of the peptides obtained from the enzymatic digestion of four different proteins with five different proteolytic enzymes.

Materials and Methods

Reagents

The proteins that were used as substrates were albumin (Mann, human fraction V), casein (Sigma, technical grade), fibrin obtained by clotting outdated blood bank plasma with thrombin and Bence Jones protein of the λ type isolated from human urine by ammonium sulfate fractionation. The enzymes used were trypsin (Worthington, TPCK treated, 200 units/mg), plasmin (KABI, human in 50% glycerol), pronase (Calbiochem, B grade, 45,000 PUK units/g), pepsin (Worthington, 3,000 units/mg) and chymotrypsin (Worthington, alpha chymotrypsin 3x crystalized).

Enzymatic Hydrolysis

Hydrolyses were carried out at 37°C for 3 hr with 1% substrate solutions. E:S was 1:1,000 except the concentration of plasmin which was 10 units/100 ml. For the pronase

hydrolysis of casein E:S was 1:100. The following buffers were used: 0.008*M* sodium phosphate, pH 7.5, for plasmin hydrolysis; 0.01*M* HCl for pepsin hydrolysis; 0.08*M* tris-HCl, pH 7.8, for chymotrypsin hydrolysis; and 0.05*M* tris-HCl, pH 8.1, for trypsin and pronase hydrolysis except for the trypsin and pronase hydrolysis of casein where 0.05*M* sodium phosphate, pH 8.1, was used.

Fractionation of Hydrolysates

The hydrolysates were centrifuged and then fractionated on Amicon ultrafilters at 4°C. The digests were first ultrafiltered using a PM 10 membrane which retains material with a molecular weight greater than 10,000. The material which passes through this membrane was again ultrafiltered using the UM 2 membrane which retains material with a molecular weight greater than 1,000. After four volumes of water have been passed through the ultrafilter the material retained by the UM 2 membrane was freeze-dried. This material constitutes the peptide fraction.

Bioassay

The bradykinin-potentiating activity of each peptide fraction was determined on the isolated guinea pig ileum as previously described.[7]

Results and Discussion

It is to be noted from Table I that bradykinin-potentiating activity was demonstrated in 19 out of the 20 peptide fractions. The peptide fraction obtained from the plasmin digest of fibrin did not exhibit appreciable bradykinin-potentiating activity but since such hydrolysates have previously been reported to possess bradykinin-potentiating activity[4] it is suggested that the active peptides may have been of a different size than those presently studied. Hamberg and Stelwagen suggested that the bradykinin-potentiating activity of tryptic peptides was due to the basic C-terminal amino acid residue. The fact that peptides produced by the action of pronase, pepsin and chymotrypsin also have bradykinin-potentiating activity would suggest that this activity is due to the amino acid sequence of the peptide rather than to its having a basic C-terminal residue.

Table I

Bradykinin-Potentiating Activity
of the Peptide Fractions

	*Amount Required for 2-fold Potentiation (μg/ml)**			
Enzyme	*Bence Jones*	*Albumin*	*Fibrin*	*Casein*
Trypsin	300	100	150	300
Pronase	350	400	300	200
Pepsin	500	100	200	80
Plasmin	300	450	N.A.	65
Chymotrypsin	500	450	150	100

N.A. - Not active at 500 μg/ml.

*Bradykinin-potentiating activity is expressed as the concentration of peptide, μg/ml of bath solution, required to increase the effect of a dose (x) of bradykinin to match the effect of a double dose (2x). Thus the potentiating activity is inversely proportional to the dose required for 2-fold potentiation.

SYMPOSIUM DISCUSSIONS

Summarized by Johannes Meienhofer

A DISCOURSE AROSE about interpreting the large negative rotation of antamanide (pp 377 to 396), *e.g.* in dioxane, in terms of bent amide bonds. This interpretation was based on examinations of *N*-acetylprolinamide derivatives and on comparisons with CD spectra of enniatine, but other interpretations might also be possible. Shifts of negative CD absorption to a positive absorption indicate in proline peptide bonds *trans* to *cis* isomerization, and this could be suggestive but not conclusive evidence for the type of transformation occurring in antamanide when changing from the uncomplexed to the complexed form.

The complete structure elucidation of the pentadecapeptide amide scotophobin still requires the determination of acid or amide functions in positions 2 (Asx), 5 and 11 (Glx). Two of eight possible isomers were prepared by solid-phase synthesis, and one was found to exhibit high biological activity (pp 397 to 402). An argument about the validity of scotophobin assays arose which could not be resolved, but it was agreed that even full biological activity does not *per se* establish identity with natural scotophobin because one or more of the other not yet prepared analogs might also be active. It was suggested that the mass spectral analysis of the synthetic products might provide further information about their relationship to natural scotophobin. With respect to the biological role of scotophobin, the question arose whether the information for fear of darkness might be contained in the peptide or whether the information might be present in the brain and the peptide effects its release.

Several suggestions were made for further chemical studies on the interesting phagocytosis stimulating tetrapeptide tuftsin (pp 403 to 407), but further work will have

to await the isolation of more material. This will be laborious because tuftsin occurs only in nanomolar quantities and elicits its activity at levels of 0.05 μg/ml. It is assumed that cyclic AMP plays a role in its mechanism of action. Tuftsin is linked to the heavy chain of a γ-globulin carrier by an ester bond between a protein carboxyl and the hydroxyl group of tuftsin's *N*-terminal threonine. In response to an inquiry about the danger of an *O→N* shift, the audience learned that this shift does indeed occur during isolation of the tuftsin-globulin complex to an extent that the recovery of ester is in the range of 15-18%.

The interesting comparison of nerve growth factor (NGF) with insulin (pp 423 to 439) stimulated a lively discussion about bioassay procedures, about the observation that NGF has an almost equal tendency to aggregate as insulin, and, therefore, commonly occurs as a dimer, and about the amount of cross-reactivity of the two proteins in radioimmunoassays which amounts to 5-10%. Concerning attachment of proteins through their amino groups to Sepharose by cyanogen bromide, it was pointed out that at pH values above 5 release of protein was observed at rates of nanomoles/min to micromoles/min. The breakage was found to occur at the attachment site and was probably effected by neighboring hydroxyl groups. Another discussant revealed that concern about this problem led to the use of crosslinked agarose. If the cyanogen bromide coupling is carried out at pH 9-10 instead of at previously employed pH 11, one can obtain very stable bonding and no release of protein occurs. The application of statistical analysis to the examination of homologies between NGF and insulin (pp 423 to 439) was welcomed by a discussant, because serious studies should confine comparisons between proteins to those parts of the sequences that have statistical significance.

In a discourse following the paper on the comparative contractile actions of vasopressin analogs on vascular smooth muscle (pp 441 to 447) auto inhibitory effects, frequently observed in dose-response curves above an optimal concentration, were mentioned. Apparently such effects vary between different blood vessels in the dog and the same analog may show no auto inhibition at all at some vessels but an even increased effect in others. These varying responses among several analogs might be construed as evidence for a second type of receptor which subserves relaxation. It was also observed that several analogs with lower intrinsic activities possessed much higher affinities. These phenomena are not surprising, a discussant pointed out, if one assumes a mechanism of action

in which the process of binding is not identical with the process of stimulus initiation, perhaps involving separate molecular regions. V. du Vigneaud reminisced on how some pharmacologists at a Federation Meeting in the early fifties argued passionately in favor of changing the name "vasopressin" to "antidiurethin."

CHEMISTRY AND BIOLOGY OF PEPTIDES

PHYSIOLOGICAL ROLES OF ANGIOTENSIN

Michael J. Peach. Department of Pharmacology, University of Virginia, School of Medicine, Charlottesville, Virginia

SUMMARY--The proteolytic enzyme renin splits an α_2-globulin to produce angiotensin I. Angiotensin II is a product formed from angiotensin I by converting enzyme. Acute injections of angiotensin II produce an increase in systolic/diastolic blood pressure. The peptide can induce an elevation of blood pressure for hours or days when administered by infusion. Angiotensin causes marked vasoconstriction in splanchnic, coronary, hepatic and cutaneous vascular beds while blood flow in the uterus, brain and skeletal muscle may increase. In pressor structure-activity-studies, amino acid residues #4, 6, 7 and 8 represent important activity sites. Angiotensin II causes a positive chronotropic cardiac response via stimulation of the sympathetic innervation of the myocardium. Angiotensin-induced increases in myocardial contractile force represents a direct effect of the peptide on cardiac muscle. Structure-activity-relationship studies in the papillary muscle indicate that proline is not required as the #7 amino acid residue. Angiotensin also interacts with the nervous systems. A central neurogenic vasconstrictor response to angiotensin has been well documented. These central effects are mediated via increased efferent sympathetic activity. Angiotensin also stimulates the adrenal medulla and autonomic ganglia and facilitates peripheral sympathetic nervous transmission. Structural requirements established for angiotensin-induced adrenal catecholamine release indicate that a C-terminal aromatic amino acid is not necessary for stimulus-secretion coupling. Autonomic ganglia also do not discriminate C-terminal

structural changes that markedly alter smooth muscle contractile responses. Angiotensin stimulates the biosynthesis of aldosterone in the adrenal cortex. The peptide appears to stimulate the first step in the biosynthesis of aldosterone; the conversion of cholesterol to pregnenolone. Preliminary structure-activity studies in the adrenal cortex indicate that a metabolite of angiotensin II, des-asp^{1}-angiotensin II (heptapeptide); is at least as active as the octapeptide in stimulating the synthesis and release of aldosterone. Analogs of angiotensin II with C-terminal aliphatic amino acids substituted for phenylalanine inhibit smooth muscle, papillary muscle, adrenal medullary, autonomic ganglia and adrenal cortical responses to angiotensin II.

FORMATION AND DEGRADATION--The name of this small, remarkably active peptide describes the activity for which it is best known (angio=vessel, tensin=tension). The peptide, angiotensin II, is the product of 2 enzymatic reactions. Renal[1,2] and possibly other tissues (*i.e.* placenta, uterus, salivary gland, brain)[3-6] contain a proteolytic enzyme called renin. Renin substrate is an α_2-globulin and the product of this reaction is a decapeptide designated angiotensin I. Angiotensin I is the substrate for a dipeptidyl carboxypeptidase (converting enzyme) and this reaction yields an octapeptide, angiotensin II, and histidyl-leucine.[7]

Endogenous or exogenous angiotensin II is rapidly degraded by plasma and possibly tissue enzymes. Three plasma enzymes have been described. (1) Angiotensinase A_1, is an aminopeptidase specific for N-terminal asparagine. This enzyme is inhibited by EDTA, has a pH optimum of 7.4 and is stable at 60°C for 30 min.[8,9] (2) Angiotensinase A_2 is an aminopeptidase specific for N-terminal aspartic acid. It is also inhibited by EDTA, has a pH optimum of 6.8 and is heat labile.[9] (3) Angiotensinase B is an endopeptidase that splits the molecule into 2 tetrapeptides. This enzyme[10] is inhibited by DPF and has no activity at physiological pH. A tissue carboxypeptidase that metabolizes angiotensin II has been isolated from liver and kidney and is called angiotensinase C.[11,12] A summary of this brief presentation is shown in Figure 1. All work in this area has been reviewed recently by Page and McCubbin[13] and Fisher.[14]

R, α_2-globulin.

Effects on the Cardiovascular System

Arterial Blood Pressure

The response to intravenous injections of angiotensin II in all species studied is characterized by about a 20 sec lag period followed by a sharp rise in systolic-distolic pressure. This increase reaches maximum in 1-2 min and declines to the initial level in 3-5 min.[15] The response to small doses is constant and repeatable while large doses produce tachyphylaxis.[16] Intraarterial injections of angiotensin II produce less of an effect on blood pressure than intravenous doses.[17] Angiotensin pressor responses induce a reflex bradycardia which is mediated by the vagus[18,19] and is blocked by treatment with atropine. Representative arterial blood pressure and heart rate responses to angiotensin II before and after treatment with atropine are presented in Figure 2.

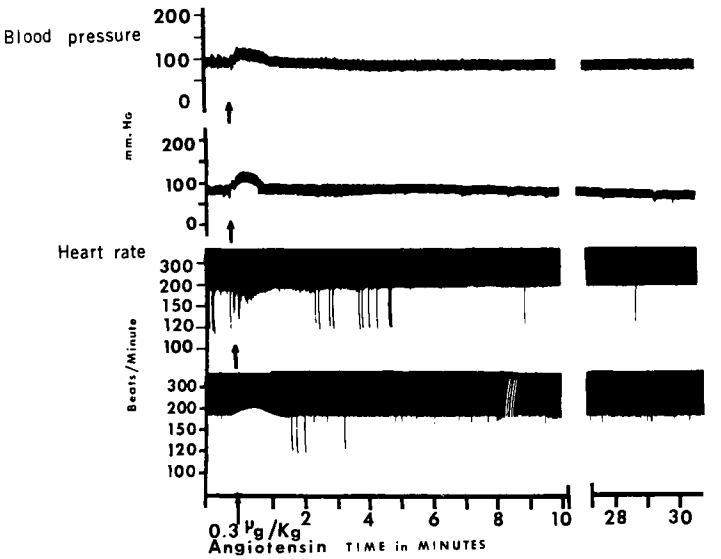

Figure 2: Representative femoral arterial blood pressure and heart rate responses to 0.3 µg/kg intravenous angiotensin II in the rabbit. The upper blood pressure recording is control and the lower recording is from the same animal after treatment with atropine, 0.5 mg/kg. Heart rate recordings also depict responses before (upper tracing) and after (lower tracing) atropine treatment.

Angiotensin can induce an elevation of blood pressure for hours or days when administered by intravenous infusion. Very low, acutely subpressor doses of angiotensin produce a slow progressive rise in arterial pressure[20,21] while doses of peptide that cause an immediate pressor response tend to lose their effect over a period of days unless the dose is continuously increased.[22,23]

Regional Blood Flow

Blood flow responses to angiotensin differ qualitatively and quantitatively in different vascular regions. Antiotensin reduces mesenteric blood flow in the cat, dog and man apparently by a constrictor effect on small arteries.[24,26] In studies with perfused hind-limbs of rabbit, rat, cat and dog, angiotensin produces a vasoconstriction.[27-29] Coronary vasoconstriction occurs in isolated perfused hearts,[30] heart-lung preparations[31] and *in vivo* in the cat[24] and dog.[32] There is an increase in blood flow in the uterus of dogs and sheep following angiotensin administration. When the peptide is administered intravenously in dogs and cats there is an initial increase in skeletal muscle blood flow.[24-34] In the cat this vasodilatation is inhibited by β-adrenergic blockade and adrenal ligation.[34,35] Cutaneous temperature and blood flow are reduced by angiotensin due to a vasoconstrictor effect on cutaneous vessels.[26,36] Cerebral blood flow in the rat is increased by the administration of angiotensin.[37] In summary, angiotensin causes marked vasoconstriction in splanchnic,[3] coronary, heptatic and cutaneous areas while blood flow in the uterus, brain and skeletal muscle may increase. In regional vascular beds where blood flow increases, this may simply reflect an elevation in tissue perfusion pressure and not any direct effect of angiotensin on the vasculature of these tissues.

Pressor Structure-Activity Relationships

Structure-activity relationship studies with pressor and oxytocic assays have recently been reviewed.[13] The following is a summary of the structural requirements of angiotensin for activity in vascular and uterine smooth muscle: (1) There must be at least 6 amino acids (residues 3-8 of angiotensin II) in the peptide chain; (2) The presence of 8 amino acid residues (angiotensin II) yields maximum activity; (3) A tyrosine residue is required in position 4 of angiotensin II; (4) The imidazole ring of histidine is required in position 6; (5) Proline must be

adjacent to position 8; (6) An aromatic amino acid with free carboxyl must be in position 8.

Heart

Chronotropic Effects

In vivo administration of angiotensin produces a reflex bradycardia.[18-19] If vagal tone is inhibited, angiotensin induces a tachycardia. Tachycardia is markedly reduced by β-adrenergic blockade, cardiac denervation or pretreatment with reserpine.[38,39] This positive chronotropic effect appears to be due to the release of norepinephrine from sympathetic neurons in the heart and not dependent on release of adrenal medullary catecholamines.[40,41] Some studies indicate that the tachycardia is due to angiotensin-induced stimulation of the stellate[42] or caudal cervical ganglia[43] while other reports suggest a direct effect on adrenergic nerve endings.[44,45]

In isolated perfused rabbit heart[46] or spontaneously beating atria[47] angiotensin has no effect on cardiac rate. This supports the suggestion that the tachycardia induced by angiotensin is dependent on an intact sympathetic innervation of the myocardium. Large doses of angiotensin prevent or reverse ventricular fibrillation induced by chloroform, epinephrine[48] and toxic doses of g-strophanthin.[49]

Inotropic Effects

Angiotensin has a positive inotropic effect in dog heart-lung preparation,[31] perfused cat heart,[50] isolated cat papillary muscle[51,52] and isolated atria from cat, guinea pig and rabbit.[47,53,54] In most of these preparations responses are obtained with 10^{-10} to 10^{-9} *M* angiotensin. The positive inotropic effect of the peptide was not altered by lowering the Ca^{2+} concentration from 2.54 to 0.63 *mM*, however, the effect was decreased at 100 *mM* Na^{+} concentration and increased at 160 *mM* Na^{+}.[55] Angiotensin-induced increases in contractile force are not affected by reserpine pretreatment[31,47,52,55] β-adrenergic blockade,[51] and extrinsic cardiac denervation[50] indicating the peptide has a direct effect on the myocardium. Hypoxia does not depress responses to angiotensin II in the cat papillary muscle.[56]

In vivo angiotensin probably exerts both this direct inotropic effect and indirect inotropic activity via stimulation of the sympathoadrenal system.[34,43,57]

Structure-Activity-Studies in Papillary Muscle

The effects of angiotensin I, angiotensin II, angiotensin II-amide, des-(Asp[1])-angiotensin II and des-(Asp[1], Arg[2])-angiotensin II on contractility of the papillary muscle are presented in Figure 3. All these peptides, with

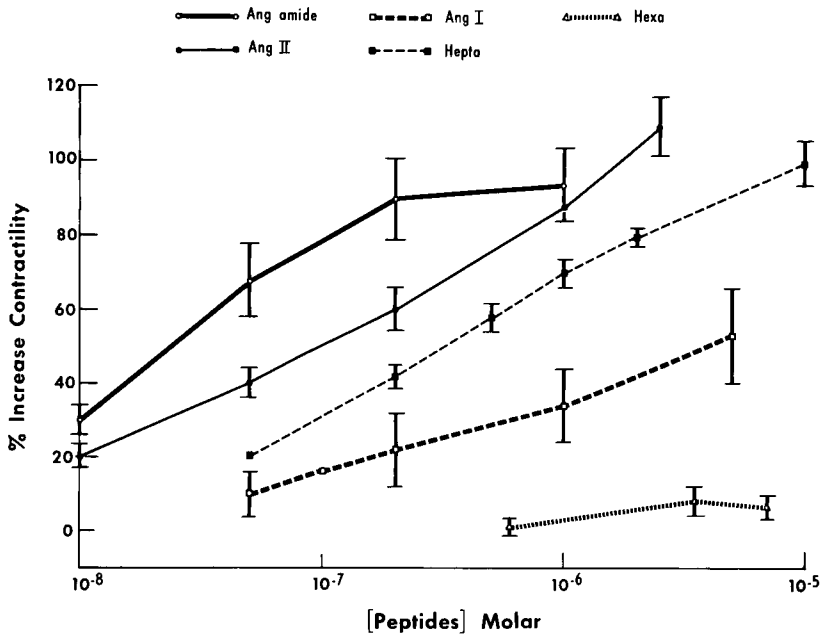

Figure 3: Comparison of the effects of angiotensin II-amide, angiotensin II, angiotensin I, hepta- and hexapeptides on myocardial contractility. Each point represents the mean ± S.E.M. of 8-12 experimental observations. Isolated papillary muscles were used in the study. Muscles were maintained at 35°C and paced by field stimulation at 60 beats/min with twice threshold voltage. Isotonic contractions were recorded from a base of 1 gram resting tension. Doses of each peptide are shown as molar concentration for ease of comparison.

the exception of hexapeptide, produced dose-dependent responses. Angiotensin II-amide was more potent than angiotensin II at concentrations from 10^{-9} to 3 x 10^{-7} *M*; however, there was no difference between these 2 octapeptides at

concentrations of $10^{-6}M$ or greater. The heptapeptide [des-(Asp^1)-angiotensin II] was not as potent as angiotensin II (about 60% relative activity at any concentration studied) but did exert marked positive inotropic activity. Angiotensin I produced an increase in contractility at concentrations about 5 x $10^{-8}M$. Angiotensin I was about 30% as active as angiotensin II. This positive inotropic effect of angiotensin I was markedly reduced (80%) by the addition of *Bothrops jararaca* pentapeptide, an inhibitor of converting enzyme.

Data obtained from the papillary assay using analogs of angiotensin with single substitutions of amino acid residues 1 through 8 are shown in Table I. Of particular interest

Table I

Comparison of Activities of Angiotensin Analogs in Uterus and Heart

Peptide	*Per Cent Activity Relative to Angiotensin II*	
	Uterus	*Papillary Muscle*
[Ile^1]-A II	20	40
[Arg^1]-A II	55	75
(Poly-*O*-acetylseryl)-A II	40	90
[Ala^3]-A II	30	100
[Tyr(OMe)^4]-A II	1	8
[Ala^5]-A II	5	30
[Ala^6]-A II	0.1	1
[Ala^7]-A II	0.1	50
[Hyp^7]-A II	5	50
[Ile^8]-A II	1	1

is the remarkable activity displayed by 3 of these analogs, (poly-*O*-acetyl-seryl)-angiotensin II, [Ala^7]-angiotensin II and [Hyp^7]-angiotensin II. The poly-*O*-acetyl-seryl analog has a molecular weight of approximately 27,000 and should not cross a cell membrane, however, on a molar comparison it was not different from angiotensin II. The two

7-substituted analogs appear to be specific stimulants of myocardial contractility.

The positive inotropic effects of angiotensin II are antagonized by [Ile^8]-angiotensin II. This data is presented in Table II. Other studies have reported that

Table II

Inhibition of Angiotensin II-Induced Inotropic Responses by [Ile^8]-Angiotensin II

	Per Cent Increase in Contractile Force

*$p<0.01$.

[Ile^8]-angiotensin II blocks the myotropic effects of angiotensin II in smooth muscle.[58-59] An effective blockade in the papillary muscle is achieved with $3x10^{-8}M$ [Ile^8]-angiotensin II.

The structural studies in the papillary muscle indicate that proline is not required in position 7, which is a requirement in smooth muscle. The minimum chain length that is effective is 7 amino acid residues instead of 6 residues. It has been reported that the heptapeptide, des-(Asp^1)-angiotensin II, is much more active in hypoxic papillary muscle than it is in muscle at normal oxygen tension.[56]

Effects on the Nervous System

Central Nervous System

Bickerton and Buckley[60] first reported a central neurogenic vasoconstrictor response to angiotensin in 1961. This study involved cross-perfusion experiments in which a donor animal supplied blood to the head of a recipient. The head of the recipient received no blood from its own cardiovascular system but the nervous system of the recipient was intact. When angiotensin II was injected into the circulation of the donor or into the aterial supply to the head of the recipient a systemic pressor response resulted in the recipient. Since this systemic response was blocked by an α-adrenergic blocking agent, they concluded that angiotensin induced a central hypertensive effect mediated via the sympathetic nervous system. It was reported later that the central cardiovascular effects of angiotensin were greatly potentiated by β-adrenergic blockade with pronetholol.[61] The entire response was shown to be only partially dependent on the sympathetic nervous system since acute surgical sympathectomy reduced but did not abolish the response. These early experiments were not fully appreciated because of the large unphysiological doses of angiotensin required. Further studies revealed that when angiotensin was infused into the vertebral circulation of the unanesthetized rabbit hypertension resulted.[62] The dose of angiotensin that produced a centrally mediated pressor response had no effect when administered systemically. Several studies have now been reported from different laboratories and they all indicated that the central effects of angiotensin are mainly mediated by increased efferent sympathetic activity.[63-66] Fukyjama *et al.*[67] and Sweet *et al.*[68] have reported that the central hypertensive effect of angiotensin persisted when the peptide was administered continuously for 7 days. The studies of Ferrario *et al.*[69] indicated that these centrally induced pressor responses are due to an increase in total peripheral resistance. Microinjections of angiotensin into the area postrema on the caudal medulla resulted in a systemic pressor response.[70] Bilateral ablation of the area postrema in the dog completely abolished pressor responses to infusions of angiotensin into the vertebral arteries.[71,72] Recently it was reported that ablation of the area postrema also attenuated pressor responses to *i.v.* infusion of angiotensin.[73]

In the cat, angiotensin-induced central pressor responses occur when the peptide is administered intraventricularly.[63, 74,75] Deuben and Buckly[76] reported that the central site

of action of angiotensin in the cat was the subnucleus medialis or nucleus mesencephalicus profundus.

Sympathoadrenal System

Sympathetic Nervous System

Studies in the early 1960's with cross-perfusion experiments,[60] ganglionic stimulation[77] and acute, surgical sympathectomy[29] suggested an interrelationship between angiotensin and the sympathetic nervous system. In 1963, McCubbin and Page[78] reported that angiotensin potentiated responses to drugs or reflexes that induced the release of norepinephrine. Benelli *et al.*[79] reported that angiotensin potentiated responses to nerve stimulation in the guinea pig vas deferens and cat spleen. Angiotensin-induced enhanced responses have also been reported in perfused mesenteric blood vessels,[80,81] perfused spleen following tyramine administration[82,83] and perfused rabbit ear with norepinephrine and tyramine.[84] Responses to tyramine in isolated aortic strips[85] and rabbit atria[47] are also potentiated by angiotensin administration. Angiotensin-induced facilitation can be blocked by α-adrenergic receptor blockade,[85,86] inhibition of norepinephrine release with bretylium[85] or depletion of norepinephrine stores with reserpine pretreatment.[85]

These effects of angiotensin on the peripheral adrenergic system occur with concentrations of angiotensin that have no direct effects on the assay organs. Angiotensin stimulates the biosynthesis of norepinephrine[87,88] in sympathetic neurons presumably by interfering with end-product inhibition of tyrosine hydroxylase, the rate limiting enzyme in the synthesis of adrenergic transmitter.

There are essentially two theories proposed to explain the mechanism of this interaction of angiotensin with peripheral sympathetic neurons. Evidence has been presented that angiotensin partially inhibits the neuronal uptake of norepinephrine.[41,46,81,89,90] Since uptake inhibition potentiates responses to norepinephrine this could explain facilitation induced by angiotensin. Structure-activity-relationship studies on uptake inhibition of norepinephrine in perfused heart[46] led us to postulate at least two receptors for angiotensin. This suggestion was based on activities displayed by several 8-substituted angiotensin analogs that did not correlate with activities from pressor/oxytocic assays. These studies also initiated a revitilization of studies with angiotensin analogs.

The second mechanism proposed to explain the interaction of angiotensin with sympathetic nerves is that angiotensin releases norepinephrine or sensitizes the neuron so that more norepinephrine is released per stimulus frequency.[79,91-94] Regardless of the exact mechanism, the evidence is overwhelming that angiotensin does modulate peripheral sympathetic activity resulting in an increase in the concentration of norepinephrine at the effector organ.

Adrenal Medulla

Release of adrenal catecholamines by angiotensin was first demonstrated in 1940, by Braun-Menendez *et al.*[95] using a crude peptide preparation. In 1959, Haas and Goldblatt[96] showed that infusions of a ganglionic stimulant, dimethylphenylpiperazinium iodide (DMPP), potentiated cardiovascular responses to angiotensin II. This DMPP-induced facilitation of responses to angiotensin II was abolished by bilateral adrenalectomy or administration of an α-adrenergic blocking agent phentolamine.[77]

Adrenalectomy in rats was reported to decrease the vasopressor action of angiotensin II, and direct perfusion of rat adrenals with angiotensin II caused an increase in catecholamine output.[97] Feldberg and Lewis (1964) demonstrated that injections of angiotensin II into the central stump of the celiac artery in the eviscerated cat induced marked adrenal catecholamine release.[98] In a subsequent study the intravenous administration of renin was reported to induce the secretion of adrenal catecholamines.[99]

In vivo studies in the dog estimating plasma catecholamines indicated that angiotensin II (*i.v.* infusion 0.05 μg/kg/min or *i.v.* injections of 0.5 μg/kg) evoked adrenal catecholamine release.[100] Other *in vivo*[101-102] *in situ*[103] and *in vitro*[104-105] studies on adrenal chromaffin stimulation by angiotensin II are in agreement with the findings of Feldberg and Lewis.[98]

Angiotensin II-induced adrenal medulla stimulation is not inhibited by bilateral splanchnicotomy, spinal block with a local anesthetic or the administration of hexamethonium, pentolinium, morphine, 5-hydroxytryptamine, histamine, bradykinin, kalliden and eledoisin.[99,102,106] In isolated adrenal medullary cells of the gerbil, angiotensin II has been shown to depolarize the chromaffin cell membrane.[107] This depolarizing effect was not altered by the administration of hexamethonium and atropine in doses that completely inhibited acetylcholine-, nicotine- and pilocarpine-induced membrane depolarization. All these

studies indicate that angiotensin has a direct stimulatory effect on adrenal chromaffin tissue.

In the *in situ* perfused adrenal of the cat, Poisner and Douglas (1966) reported that Ca^{2+} was required for release of catecholamines by angiotensin II. This requirement for extracellular Ca^{2+} was confirmed in the isolated dog[104] and cat adrenal.[108] It would appear that angiotensin depolarizes the chromaffin cell membrane which then results in a net transfer of extracellular Ca^{2+} into the cell. It is not known if angiotensin has the ability to effect the translocation of intracellular Ca^{2+} and induce secretion-coupling without depolarizing the cell membrane; however, this would seem unlikely.

Analogs of angiotensin have been studied in the adrenal medulla and their activities relative to angiotensin have been determined.[95,102,105,108] Structural requirements established for stimulation of medullary catecholamine secretion are as follows: (1) there must be at least 6 amino acids in the peptide chain (residues 3-8 of angiotensin II); (2) a tyrosine residue is required in position 4 of the angiotensin II molecule; (3) the imidazole ring of histidine must be in position 6; and (4) proline must be adjacent to position 8.

Stimulation of adrenal chromaffin tissue by angiotensin can be blocked by several 8-substituted analogs, as [Leu^8]-angiotensin II, [Val^8]-angiotensin II, [Ile^8]-angiotensin II, [8-cyclohexylalanine]-angiotensin II. Inhibition of angiotensin-induced secretion of adrenal catecholamines by [Ile^8]-angiotensin II is shown in Figure 4. This 8-substituted analog is a competitive inhibitor of angiotensin in the adrenal medulla.

Parasympathetic Nervous System and Autonomic Ganglia

Part of the contractile response induced by angiotensin in isolated intestinal strips is due to the release of acetycholine from the enteric nerve plexus in the intestine.[109,110] The contraction of guinea pig ileum in response to angiotensin is a composite of two effects.[111] There is a fast component manifested as a rapid rise in tension and subsequent partial relaxation. The second effect is a slow, progressive contraction that reaches maximum in about 2 min. The initial rapid component can be blocked by atropine and morphine and potentiated by acetycholinesterase inhibitors.[112,113]

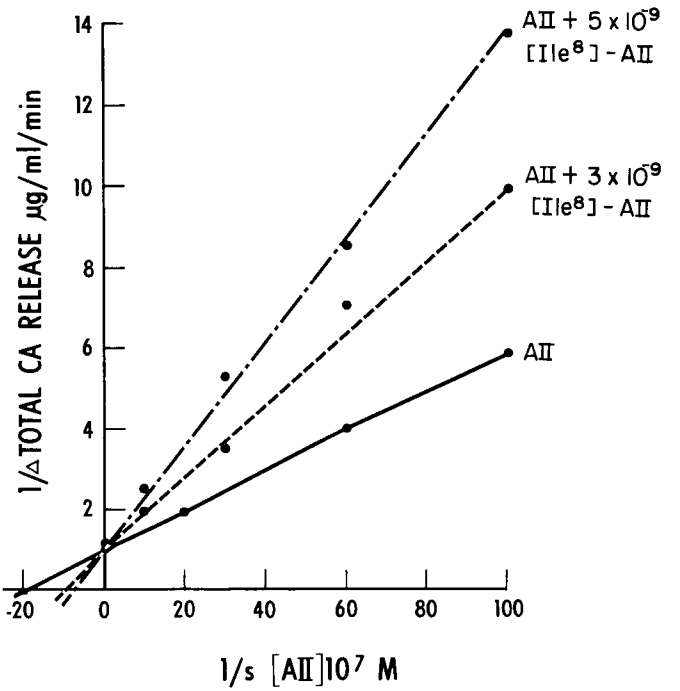

Figure 4: Inhibition of angiotensin II-induced adrenal catecholamine release by [Ile^8]-angiotensin II. Studies were carried out in the isolated retrograde perfused adrenal of the cat. Each point represents the mean determined from 6-10 experimental observations. The 8-substituted analog is a competitive inhibitor of angiotensin II.

In 1965, Lewis and Reit[114] first reported that close intraarterial injections of angiotensin to the superior cervical ganglion of cats produced a contraction of the nictitating membrane. This angiotensin-induced response was prevented by sectioning the postganglionic nerve but was unaffected by chronic decentralization. Ganglionic responses to angiotensin were unimpaired by treatment with hexamethonium and atropine. Further studies showed that morphine[115] and depolarization phase nicotine blockage prevented[115,116] angiotensin-induced ganglionic stimulation. During non-depolarization phase nicotine blockade of the

ganglion[115,116] or following a burst of high frequency preganglionic stimuli,[115,116] ganglionic responses to angiotensin were markedly potentiated. Angiotensin had very weak activity on the superior cervical ganglion of rabbits and no activity in dogs.[115] Angiotensin can also facilitate responses to preganglionic stimulation in the superior cervical ganglion of the cat.[117-119] This facilitation is felt to be due to increased release of acetylcholine from the preganglionic neuron.[120] Angiotensin has also been shown to stimulate the stellate ganglion in the cat.[42,121] This stimulatory effect in the stellate is only on the adrenergic ganglion cells resulting in cardioacceleration.[121] Angiotensin-induced ganglionic stimulation leading to cardiac stimulation has also been reported in the dog,[39,43] however, the ganglion involved was the caudocervical instead of the stellate.

There have been two structure-activity studies in autonomic ganglia, one, in the superior cervical ganglion[115] and, the other, in the enteric plexus of the intestine.[122] Ganglionic activities of one *N*-terminal substituted analog and two peptides with changes in position 4 correlated well with activities displayed in the adrenal medulla and on blood pressure.[115] Khairallah *et al.*[122] studied ten analogs of angiotensin in the guinea pig ileum. With substitutions of residues 1 to 7, they reported a parallelism between pressor responses and both the direct myotropic and acetylcholine-mediated responses of the ileum. Substitutions in position 8 yielded analogs with activities that did not parallel pressor responses induced by these peptides. The smooth muscle of the ileum appeared to discriminate between phenylalanine, tyrosine and *p*-methoxy-tyrosine substitutions in position 8 but the parasympathetic neurons did not. [Ala^8]-angiotensin II completely blocked both components of angiotensin-induced contraction of the ileum. This represented the first indication that aliphatic amino acids substituted for phenylalanine yield competitive inhibitors of angiotensin II.

Adrenal Cortex

Stimulation of Aldosterone

In cross circulation studies, blood from dogs with secondary hyperaldosteronism[123] or from sodium-depleted sheep[124] produced secretion of aldosterone in normal recipients. Further experiments showed that the kidney was involved in aldosterone production induced by acute

hemorrhage.[125] It was also reported that the administration of angiotension II stimulated aldosterone secretion *in vivo*.[126] Stimulation of aldosterone was specific for angiotensin, and not for other pressor agents, with maximum stimulation occurring at moderately pressor doses of the peptide.[127,128] The effect of angiotensin in the adrenal cortex was shown to be direct in studies that showed a marked increase in aldosterone secretion in slices of bovine adrenal[129] and isolated, perfused adrenals of dogs.[130] Antibodies to renin were shown to block aldosterone secretion induced by the administration of renin.[131] Renal and plasma renin was found to be increased in dogs with caval constriction[132] or animals on low sodium diets.[133] Adrenal cortical reponses to angiotensin can be reduced by an elevation of plasma sodium content.[134] High sodium and/or low potassium concentration appears to inhibit the stimulatory effect of angiotensin on the adrenal cortex.[135-137] The rat appears to be the one species in which angiotensin has a very weak effect on the adrenal cortex.[138]

Angiotensin appears to stimulate the first steps in the biosynthesis of aldosterone--probably the conversion of cholesterol to pregnenolone.[129,139,140] In addition, chronic sodium depletion[141] or renin administration[140] increases the conversion of corticosterone to adlosterone without altering 11-hydroxylase activity. With acute angiotensin administration or *in vitro* the peptide has no effect on corticosterone conversion to aldosterone.[129,138,139,141]

Structure-Activity-Relationship Studies

Only two structure-activity-studies have been reported with angiotensin and the adrenal cortex. The first study by Hageman *et al.*[142] used a 6-substituted analog, [6-B-(pyrazolyl-3)-1-alanine]-angiotensin II. Its activity relative to the parent octapeptide showed good correlation of induced aldosterone secretion in the dog with activity in several other assays. The second study by Blair-West *et al.*[143] determined the effects of heptapeptide, des-(Asp^1)-angiotensin II, and hexapeptide, des-(Asp^1,Arg^2)-angiotensin II, on aldosterone secretion *in vivo*. The heptapeptide was as active as angiotensin II in stimulating aldosterone secretion while the hexapeptide was totally inactive. This potent effect of the heptapeptide suggests a possible physiological role for the metabolite of angiotensin II. In preliminary studies (Chiu and Peach, unpublished observations) with adrenal cortical cell suspensions of dog adrenal, the heptapeptide on a molar basis is more potent than angiotensin II

in stimulating incorporation of H^3-cholesterol into H^3-aldosterone. Stimulation of aldosterone biosynthesis can be blocked by [Ile^8]-angiotensin II (Peach unpublished observation).

In summary, one must realize that by no means does this presentation cover all the activities reported for angiotensin. The three general activities of angiotensin covered in some detail here, stimulation of the cardiovascular system, nervous system, and adrenal cortex, do represent effects of the peptide that are felt to be important to understanding the various roles of angiotensin. Angiotensin is a potent, biologically active peptide with a very broad spectrum of physiological activities. At the present time, one must consider that any one of these activities or all may represent the key to elucidating pathophysiological roles of angiotensin.

CHEMISTRY AND BIOLOGY OF PEPTIDES

FROM ANGIOTENSIN TO ANTI-ANGIOTENSIN

D. Regoli, F. Rioux, W. K. Park. Department of Pharmacology, Centre Hospitalier Universitaire, Sherbrooke, Canada

VARIOUS HORMOMES AND naturally occurring substances, like angiotensin, have a polypeptide structure. It is assumed that the groups responsible for binding a peptide to receptors or for evoking biological responses, are scattered along the side chains. As pointed out by Dickerson and Geis:[1] "If the polypeptide chain provides the fundamental pattern, the ground bass of the composition, it is the side chains that build the melody."

Identification of active groups in a peptide is the primary step for the discovery of specific antagonists. By definition an antagonist should possibly have the same affinity for the receptors as the agonist has, but be devoid of intrinsic activity.[2] A rational approach to the identification of active groups in the side chains of the various amino acids composing a peptide is the substitution of the single amino acids with presumably inactive compounds, such as Gly, Ala or unnatural amino acids with a saturated ring, like 1-amino-cyclopentanecarboxylic acid (Acpc).

In a preliminary study, a series of analogs of the octapeptide 5-Ile-angiotensin II (A II) were prepared by replacing with Acpc the amino acids in positions 1 to 8. Affinities and intrinsic activities were evaluated "in vitro" on rat isolated stomach strips suspended in a 40 ml bath or in a cascade superfusion system, according to Vane.[3] Details of the methods have been described previously.[4,5]

It was found that the replacement of 4-Tyr decreases the affinity, while the substitution of 6-His, 7-Pro and 8-Phe reduce both affinity and intrinsic activity.[4] Tests

for antagonism indicated that [Acpc^6]-A II and [Acpc^7]-A II are inactive compounds, while [Acpc^8]-A II is an inhibitor.[4] When Gly and Ala were used instead of Acpc, to replace 4-Tyr, 6-His and 7-Pro, similar effects were observed with the analogs substituted in position 4, but the intrinsic activities of [Ala^6]-A II and [Ala^7]-A II were found to be higher (see Table I) than those of analogs substituted with Gly and Acpc. Results shown in Table I indicate that the presence of an asymmetric α-carbon in positions 6 and 7 is necessary to maintain the steric orientation of the phenyl ring in position 8.

Table I

Intrinsic Activities (α^E) and Affinities (pD_2) of Various Angiotensin II (A II) Analogs, on the Rat Isolated Stomach Strip

1 2 3 4 5 6 7 8 *Asp - Arg - Val - Tyr - Ile - His - Pro - Phe*		
Compound	α^E	pD_2*
A II	1.0	8.0
[Phe^4]-A II	1.0	6.8
[Acpc^4]-A II	0.8	4.9
[Ala^4]-A II	0.9	4.8
[Gly^4]-A II	0.7	4.8
[Acpc^6]-A II	0.3	---
[Ala^6]-A II	0.9	5.0
[Gly^6]-A II	0.5	4.0
[Acpc^7]-A II	0.5	5.8
[Ala^7]-A II	1.0	6.4
[Gly^7]-A II	0.7	4.4

*Log of molar concentration

To find potent and specific antagonists of A II a series of analogs substituted in position 8 were synthesized. The compounds were tested "in vivo" (on the blood pressure of nephrectomized rats anesthetized with urethane) and "in

vitro" (on the rat isolated stomach strip, suspended in a 5 ml bath, with oxygenated Krebs solution at 37° C, to record isometric contractions).[5] Affinity of antagonists was evaluated with the method of Schild[6] by estimating pA_2. Residual intrinsic activity was measured by applying to the tissues increasing concentrations of the analogs.

As shown in Table II, the lengthening of the aliphatic chain from Ala to Leu, increases progressively the affinity

Table II

Relative Potencies of Various A II Antagonists as Determined "In Vivo" (on the Rat Blood Pressure) and "In Vitro" on the Rat Isolated Stomach Strip

A II: pD_2 = 8.00			*[Leu^8]-A II: pA_2 = 8.00*	
Compound	*ID_{50} (µg/kg/min)*	*Relative Potency in vivo*	*pA_2*	*Relative Potency in vitro*
[Gly^8]-A II	1.10	0.3	6.77	0.06
[Ala^8]-A II	1.00	0.3	6.86	0.07
[*n*-But^8]-A II	0.41	0.8	7.48	0.3
[Val^8]-A II	0.67	0.5	7.51	0.3
[Ile^8]-A II	0.36	0.9	7.90	0.8
[Leu^8]-A II	0.32	1.0	8.00	1.0
[Glu^8]-A II	10.0	0.03	6.61	0.04
[Lys^8]-A II*	100.0	0.003	----	----
[Sar^1,Leu^8]-A II	0.07	4.6	8.60	4.0
[β-Asp^1,Leu^8]-A II	0.26	1.2	8.20	1.4
[Sar^1,Ala^8]-A II	0.28	1.1	8.38	2.5

ID_{50}, Dose producing 50% of inhibition.
pA_2, Indicates -log of molar concentration.
*A preliminary analysis of this compound with infra red spectrum in a solution cell has shown a partial cyclisation.

of the antagonist for the receptors and leads to analogs ([Leu^8]-A II) with a pA_2 value (8.0) equal to the pD_2 value (8.0) of A II. These findings indicate that optimal

stimulation of the receptors requires the presence of a phenyl ring in position 8. Binding of the phenyl ring to the receptors may be due to its hydrophobic character, which is shared by the side chain of Leu, but stimulation of receptors appears to be due to the resonance of the phenyl ring, which is obviously absent in Leu.

This conclusion is supported by the results obtained with [Glu^8]-A II and [Lys^8]-A II. Replacement of 8-Phe with an acid (Glu) or a basic (Lys) hydrophilic group brings about almost inactive compounds.

Peptides hormones have generally a short half-life in the circulation, because they are rapidly taken up by the tissues and inactivated by the polypeptidases. Inactivation of a peptide can be partially prevented by substituting, at the amino end, compounds which prevent the action of aminopeptidases. It has been shown that replacement of asparagine with β or β-D aspartic acid in A II increases the potency of the analog, as well as its duration of action.[7]

To obtain long acting inhibitors of A II double substituted (in positions 1 and 8) analogs were prepared. Results are shown at the bottom of Table II. Replacement of 1-Asp with Sar or with β-Asp, increases the potency and the duration of action[8] of the antagonist. This suggests that the compounds may be slowly degraded by aminopeptidases. However, the results obtained "in vivo" with [β-Asp^1]-A II and [Sar^1]-A II (see Table III) indicate

Table III

Relative Potencies and Pharmacological Characterization of Angiotensin II (A II) [β-Asp^1]-A II and [Sar^1]-A II, "in vivo" (Rat Blood Pressure) and "in vitro" (Rat Isolated Stomach Strip)

Compounds	*"in vivo"*		*"in vitro"*		
	R.P. %	*D.A.* *min.*	α^E	pD_2	*R.P.*
A II	100	2.0 ± 0.1 (9)	1.0	8.0	100
[β-Asp^1]-A II	172	3.5 ± 0.4 (9)	1.0	8.2	150
[Sar^1]-A II	100	2.5 ± 0.2 (9)	1.0	8.3	200

α^E, Intrinsic activity. pD_2, Affinity.
In parentheses, the number of determinations.
R.P., Relative potency. D.A., Duration of action.

that degradation by aminopeptidases is probably not the primary factor involved in increasing the potency of the two antagonists [Sar^1,Leu^8]-angiotensin II and [β-Asp^1,Leu^8]-angiotensin II.

CHEMISTRY AND BIOLOGY OF PEPTIDES

COMPARATIVE PHARMACOLOGY OF ANGIOTENSIN ANTAGONISTS

Philip Needleman, Eugene M. Johnson, Jr., William Vine, Everett Flanigan, and Garland R. Marshall.* Departments of Pharmacology and of Physiology and Biophysics, Washington University School of Medicine, St. Louis, Missouri 63110

THE *IN VIVO* CONVERSION OF the decapeptide Asp^1, Val^5-angiotension I (A I) to the octapeptide angiotensin II (A II) has been shown to occur primarily in the pulmonary circulation.[1-3] A I possesses minimal biological activity whereas A II is an extremely potent substance with a wide range of effects and of course, the renin angiotensin system is implicated in renal hypertension.[4] [Phe^4-Tyr^8]-A II was the first reported specific antagonist of A II[5] and there have since been a number of A II antagonists reported.[6,7] In addition, peptides initially isolated from snake venom have proven to be potent converting enzyme inhibitors while apparently having little or no effect at A II receptor sites.[8] This investigation describes a number of peptide analogs which have been assayed for their ability to act as angiotensin antagonists both *in vitro* and *in vivo* as well as in renal hypertensive rats. Materials: The angiotensin analogs were synthesized by the solid-phase procedure of Marshall and Merrifield[9] and the compounds were purified by Sephadex chromatography and characterized by amino acid analysis. The hippuryl histidyl-leucine and SQ 20881 (Glu-Tyr-Pro-Arg-Pro-Gln-Ile-Pro-Pro) were kindly supplied by D. W. Cushman of Squibb Research Institute. [Phe^4-Tyr^8]-A II[5] [Ala^8]-A II[7] and [Ile^8]-A II[10] are the

only angiotensin analogs considered in this report that have previously been described.

Results and Discussion

Oxytocic effects of peptide analogs

Peptides which were angiotensin agonists and antagonists in uterus are described in Table I and Table II. [*p*-fluoro-Phe^4]-A II was equipotent to A II, whereas A I had only 2% of the oxytocic activity. Rat uterus is known to have minimal converting enzyme activity.[15] The octapeptide analogs ([Ile^8]-A II, [Cys^8]-A II, [Phe^4-Tyr^8]-A II and [*p*-fluoro-Phe^4]-A II) were potent competitive antagonists of A II and A I (Table I). Of special interest is that [*p*-fluoro-Phe^4]-A II represents the first antagonists which is not modified in the 8-position of angiotensin. [Ile^8]-A II, [Cys^8]-A II, A II, and [*p*-fluoro-Phe^8]-A II appear to have the same affinity for the uterine receptor site.

Table I

Effect of Angiotensin (A) Analogs as Agonists and Antagonists on Isolated Rat Uterus Strips*

Agonists		*Potent Antagonists*	
Peptide Analogs	*Km ng/ml*	*Peptide Analogs*	K_I *ng/ml*
A II	5	[Ile^8]-A II	5
[*p*-fluoro-Phe^8]-A II	5	[Cys^8]-A II	6
A I	250	[Phe^4, Tyr^8]-A II	240
		[*p*-fluoro-Phe^4]-A II	500

*Uterine segments were suspended in 5 ml of de Jalon's solution[11] which was bubbled with O_2-CO_2 (95:5%) at room temperature. K_m and K_I were calculated from reciprocal plots of gm of uterine contraction versus dose of angiotensin analogs. Each peptide was tested on 4-8 uterine strips.

Table II

Effectiveness of Octapeptide and Decapeptide Analogs as A II and A I Antagonists on Rat Uterine Strips*

Peptide Analogs	*Conc. of antagonist* μg/ml	*Angiotensin* ED_{50}
A II	0	5
A II + [Ile^8]-A I	100	50
A II + [Phe^4]-Tyr^8-A I	25	50-100
A II + [Ala^8]-A II	10	100
A I	0	250
A I + [Ile^8]-A I	100	2500
A I + [Phe^4, Tyr^8]-A I	25	2500-5000

*ED_{50} was the dose of A II or A I needed to produce a contraction which was 50% of the maximal response. Each peptide was tested on 4-8 uterine strips.

The decapeptide analogs [Phe^4-Tyr^8]-A I and [Ile^8]-A I, as well as the octapeptide [Ala^8]-A II were weak antagonists which required very high concentrations to produce comparable 10-20 fold shifts in the both A II and A I dose response curves (Table II). This data supports the conclusion that A I and A II must act at the same receptor site. If significant conversion of the decapeptides to octapeptides was occurring the compounds would have been more potent antagonists.

Conversion of peptide analogs by rabbit lung extracts

Converting enzyme activity was measured in rabbit lung acetone powder extracts by a modification[12] of the spectrophotofluorometric method of Piquilloud, *et al* [13] using either hippuryl-His-Leu or A I as the substrate.

Hippuryl-His-Leu (HHL) was used as a substrate to characterize converting enzyme activity because it is not hydrolyzed by most other tissue peptidases. The K_m for HHL with the rabbit lung acetone powder was 2.5 mmol/liter.

The decapeptides A I, [Ile^8]-A I, and [Phe^4, Tyr^8]-A I were equipotent competitive inhibitors of HHL with a K_i of 1-4 μmol/liter. Incubation of the decapeptides with rabbit lung (at concentrations comparable to that needed for HHL inhibition) did not result in the appearance of assayable His-Leu (therefore less than 2% was converted). However, the K_m of the three decapeptides when studied as substrates for the rabbit lung enzyme was 50-200 μmol/liter. The K_m's of HHL and A I agree with those previously reported.[14]

In Vivo angiotensin antagonism in normotensive rats

[Ile^8]-A II and [Cys^8]-A II were potent antagonists of the A II induced vasoconstriction in normotensive rats. When infused at 100 μg/kg/min, these two analogs caused a 200-250 fold shift in the A II dose response curve (Table III). [Phe^4, Tyr^8]-A II, and [*p*-fluoro-Phe^4]-A II were less potent antagonists causing a 10-25 fold shift in the A II dose-response curve (when antagonists were infused at 100 μg/kg/min). [Phe^4, Tyr^8]-A II and [*p*-fluoro-Phe^4]-A II possess some agonistic activity. Park and Regoli[6] demonstrated that [Ala^8]-A II and [Phe^4, Tyr^8]-A II were equipotent as A II and A I antagonists *in vivo*.

A I was essentially equipotent with A II in elevating rat blood pressure, indicating rapid *in vivo* conversion of the decapeptide to the octapeptide. [Ile^8]-A I proved to be much less potent (100 fold) as an A II antagonist than [Ile^8]-A II, thus the decapeptide appears to be a less efficient substrate *in vivo* for the rat converting enzyme (*in vivo*) than does A I (Table III). The A II inhibitory activity of [Ile^8]-A I was substantially reversed by the nonapeptide converting enzyme inhibitor SQ 20881 (Table III). SQ 20881 did not alter A II vasoconstriction but caused a 200 fold decrease in A I activity thereby indicating that there was some *in vivo* conversion of [Ile^8]-A I to the octapeptide antagonist. Aiken and Vane[15] have noted that poor correlation existed between converting enzyme activity in rat isolated organs and homogenates of those tissues.

Effect of peptides on renal hypertension

Infusion of 100 μg/kg/min of [Cys^8]-A II, [Ala^8]-A II, [Ile^8]-A II, [*p*-fluoro-Phe^4]-A II, [Phe^4, Tyr^8]-A II, as well as 50 μg/kg/min of SQ 20881 and 1 mg/kg/min of [Ile^8]-A I and [Phe^4, Tyr^8]-A I cause a 15-30% reduction in mean blood pressure which returned to the preinfusion level

Table III

Ability of Peptide Analogs to Lower Blood Pressure in Renal Hypertensive Rats and to Inhibit the A II Pressor Response in Normotensive Rats

Peptide analogs	*Dosage* μg/kg/min	*A II in presence of peptide analogs* ED_{25} μg/kg*	*Percent fall of blood pressure in renal hypertensives*†
Controls (A II or A I or [*p*-fluoro-Phe^8]-A II		0.1 (8)#

**Normotensive* rats were pentobarbital anesthetized and pretreated with phenoxybenzamine and propranolol. The analogs were infused for 15 min and throughout the A II dose response curves (given as pulse injections in the other jugular vein).

†Acute renal hypertension was produced by unclamping the left renal pedicle (contralateral kidney was left intact) which had been occluded for 4.5 hr.[16] The mean blood pressure in the phenoxybenzamine (30 mg/kg), propranolol (15 mg/kg) pentobarbital sodium (30 mg/kg), treated rats before clamp removal was 79 ± 3 and after clamp removal was 112 ± 4. The values represent the mean ± SE of blood pressure measured after 10 min of infusion.

#Numbers in parentheses represent numbers of animals used in each test.

10 min after completion of the infusion (Table III). Infusion of the combination of SQ 20881 and [Ile^8]-A I caused no further reduction in renal hypertension than either agent used alone. Such agents have potential therapeutic activity for confirmatory diagnosis in renal hypertension.

CHEMISTRY AND BIOLOGY OF PEPTIDES

HIGHLIGHTS OF RECENT STRUCTURE-ACTIVITY STUDIES WITH ANGIOTENSIN II

Robert R. Smeby, M. C. Khosla, F. Merlin Bumpus.
Research Division, Cleveland Clinic Foundation,
Cleveland, Ohio 44106

IN THE LAST FEW YEARS a large number of angiotensin II analogs have been prepared and these studies have shown that structural modifications in amino acid positions 1 through 7 usually resulted either in retention or destruction of pressor or myotropic activity. Assays of these analogs in widely differing biological systems gave results that were consistent from one assay system to another. Thus, amino acid changes in these positions, which destroy biological activity, either remove a group required to obtain binding between peptide and receptor site or destroy the conformation necessary for peptide-receptor site interaction.[1]

However, when structural modifications were made in position 8 of angiotensin II more interesting results were obtained. Thus, [8-alanine]-, [8-(3-amino-3'-phenylisobutyric acid)]-, and [8-(2-amino-4-phenylbutyric acid)]-angiotensin II exhibited low pressor activity but were found to be highly active in inhibiting uptake of catecholamines by sympathetic nerve endings and causing release of catecholamines from adrenal medulla. On the other hand, [8-tyrosine]-angiotensin II has high pressor activity but lower activity in inhibiting catecholamine uptake.[2] Later [8-alanine]-angiotensin II was shown to competitively inhibit the response of isolated muscle strips to angiotensin II[3] *in vitro* but did not inhibit the *in vivo* pressor response of the cat to angiotensin II. This analog has very low biological activity.

Increasing the size of the aliphatic side group of the amino acid in position 8 to give [8-isoleucine]-angiotensin II increased both the biological activity and the angiotensin II antagonistic activity. This analog is a potent competitive antagonist of the *in vitro* myotropic response to the parent hormone. The pressor response to angiotensin II in the dog, cat and rat is also inhibited by this analog. Infusion of this analog into rats with acute renal clip hypertension, both with the contralateral kidney intact (2 kidney) and with the contralateral kidney removed (1 kidney), caused a reduction in blood pressure. These data, shown in Table I, demonstrate that peptide analogs which inhibit angiotensin II will be very useful tools in the study of the etiology of hypertensive disease in animals and as a possible diagnostic aid in the treatment of patients with renal hypertensive disease.

Table I

Reduction of Blood Pressure in Renal Hypertensive Rats by Infusion of [8-Isoleucine]-Angiotensin II

Group	*No. in group*	*Average B.P. before infusion (mm Hg)*	*Average B.P. after infusion (mm Hg)*	*Dose infused (ng/rat/min)*	*p value*
Normotensive	7	90	94	200 and 1000	N.S.
2 Kidney Hypertensive	4	167	141	200	0.01
1 Kidney Hypertensive	7	138	115	1000	0.001

Angiotensin II increases capillary permeability in rabbit skin and this effect is also inhibited by [8-isoleucine]-angiotensin II. However, in isolated frog skin, where angiotensin II increases the rate of sodium transport, this analog is twice as active as an agonist as the natural peptide. It is not known whether this effect is due to a different type of receptor mechanism involved in the sodium transport system as compared to the muscle receptor or merely due to the change in species.

Changing the aromatic ring of phenylalanine in position 8 to a saturated ring, to give [8-cyclohexylalanine]-

angiotensin II, has yielded an analog which gives assay results difficult to interpret. The initial dose of this analog cuases a moderate pressor and myotropic response (about 25% of the parent hormone) but subsequent responses to itself or angiotensin II are abolished. It is not known whether this compound is a potent, long-lasting, competitive antagonist or whether it is making the assay system tachyphylactic. This peptide requires much further study.

Further changes in position 8 to give [8-valine]-, [8-leucine]-, and [8-norleucine]-angiotensins II have not increased the antagonistic potency of [8-isoleucine]-angiotensin II. It is interesting in this regard to note that the isoleucine side chain is very similar in size and shape to the aromatic ring of phenylalanine. Placing an unnatural amino acid in the 1 position, [1-sarcosine, 8-isoleucine]-angiotensin II increases the duration of antagonistic activity probably because the peptide is protected from the action of aminopeptidase.

Recent physical studies by Fermandjian and Fromageot[4] on some of these analogs modified in position 8 have indicated that these peptides have a conformation different from angiotensin II. It is not yet known whether the degree of conformational change can in any way be associated with the antagonistic activity. Whatever the effect of the 8-position is toward causing the specific, competitive inhibition of angiotensin II, it may not be limited to the 8-position alone because [4-phenylalanine, 8-tyrosine]-angiotensin II is an antagonist[5] while [8-tyrosine]-angiotensin II is not.

The specific, competitive inhibition produced by these analogs of angiotensin II may be highly useful for both laboratory and clinical studies of hypertensive disease. It is to be hoped that these studies will lead to future compounds which will be more potent and longer acting.

CHEMISTRY AND BIOLOGY OF PEPTIDES

RELATIONSHIPS BETWEEN PRESSOR ACTIVITY AND THE PROPERTIES OF SIDE CHAINS OF ANGIOTENSIN II

Eugene C. Jorgensen, Graham C. Windridge, Kun-Hwa Hsieh.* Department of Pharmaceutical Chemistry, School of Pharmacy, University of California, San Francisco CA 94122

Thomas C. Lee. Department of Human Physiology, School of Medicine, University of California, Davis, CA 95616

THE IMPORTANCE OF THE CARBOXYL terminal hexapeptide sequence of angiotensin II for its myotropic and pressor effects has been well established.[1] We have examined specific characteristics of the amino acid side chains within the 5-8 portion of this sequence by solid-phase synthesis of analogs of [1-asparagine,5-isoleucine]-angiotensin II. The analogs were studied for their pressor effects in the pentolinium-treated nephrectomized rat (Table I).

The 5-Isoleucine Position

Previous analog studies[2] showed that activity equal to that of angiotensin II could be produced by the replacement of isoleucine by a variety of lipophilic aliphatic and alicyclic β-branched L-α-amino acids, such as valine, allo-isoleucine α-amino-β-ethylvaleric acid, α-cyclopentylglycine, and α-cyclohexylglycine. Activity was significantly reduced when β-branching was absent in related analogs. In order to test the importance of lipophilic character for a side chain in the 5-position, the more hydrophilic β-branched

*Present Address: School of Pharmacy, Virginia Commonwealth University, Richmond, Virginia 23219.

[Asn^1,Ile^5,Nle^8]-angiotensin II	6
[Asn^1,Ile^5,Ahp^8]-angiotensin II$^\surd$	10

*Thr(Me),*O* -Methylthreonine

†A$_2$bu,2,4-diaminobutyric acid

$^\#$Pya,β-(Pyridyl-2)alanine

$^\surd$Ahp, α -Aminoheptanoic acid

5-*O*-methylthreonine and 5-threonine analogs were prepared. It was expected that the increasingly polar methyl ether and hydroxyl containing side chain analogs would show a regular decrease in activity with decreasing lipophilic character. However, [1-asparagine, 5-*O*-methylthreonine]-angiotensin II showed 118% activity relative to 100% for [1-asparagine,5-valine]-angiotensin II in the rat pressor assay. [1-Asparagine,5-threonine]-angiotensin II was 10% as active.

The equally high activity contributed by the side chains of a wide variety of highly lipophilic β-branched aliphatic and alicyclic amino acids, and by the relatively polar side chain of *O*-methylthreonine, indicates that the steric effect is of primary importance. The low activity of the more hydrophilic [5-threonine] analog may be due to its exceeding limits of hydrophobic character. However, it is believed

more likely that the free hydroxyl group produces changes in the conformation of the peptide through the formation of new hydrogen bonds.

The NMR spectra of the [Thr^5] and [Thr(Me)^5] analogs in D_2O were virtually identical for the protons of the side chains, except for the presence of the OMe singlet (3.25 ppm) in the [Thr(Me)^5] analog. The peptide backbone CH spectra (4.0-4.5 ppm) showed significant differences between the analogs, although a more detailed study would be required to identify these with specific conformational differences.

The 6-Histidine Position

The imidazole ring of histidine possesses a number of characteristics which have been associated with its functional role in enzymes, such as aromatic character, acid-base behavior, and hydrogen donor and hydrogen acceptor ability in hydrogen bond formation.

The need for aromatic character was indicated by the low activities for the neutral [6-alanine] analog (0.8%),[3] and for the [6-lysine] analog (0.1%)[4] in which a basic nitrogen atom was placed at a spacing which approximates that of the *tele*-nitrogen of histidine. We have prepared the [6-(2,4-diaminobutyric acid)] analog in which the basic nitrogen approximates the position of the *pros*-nitrogen of the imidazole ring. [1-Asparagine,5-isoleucine,6-(2,4-diaminobutyric acid)]-angiotensin II shows negligible activity (0.02%) in the rat pressor assay.

Aromatic character alone is not sufficient as has been shown by the low activities for the [6-phenylalanine] (1%)[5] and [6-thienylalanine] (1%)[6] analogs. That acid-base behavior is not a critical function of the imidazole ring was shown with the weakly basic ($pK_a \sim 2.5$) but highly active (57%, rat pressor) [6-β-(pyrazolyl-3)-alanine] analog.[7] To extend this heterocyclic series we have prepared the more basic [6-β-(pyridyl-2)-alanine] analog in which the pyridine ring has a pK_a of about 6.0. [1-Asparagine,5-isoleucine,6-β-(pyridyl-2)-alanine]-angiotensin II showed 3% activity in the rat pressor assay.

Two correlative physical properties are present in the N-heterocyclic series. The highly active imidazole and pyrazole analogs have high dipolar character, and possess tautomeric forms with a pyrrole-like NH in the *pros*-position adjacent to the side chain. These features could facilitate the intramolecular interaction between the imidazole ring and phenylalanyl carboxylate ion demonstrated for the active

analog, des-Asp^1-[Gly^2,Ile^5]-angiotensin II,[8] and thus help to stabilize an active conformation.

In the solid-phase synthesis, incorporation of Boc-β-(pyridyl-2)-L-alanine in methylene chloride with dicyclohexylcarbodiimide and 1-hydroxybenzotriazole, under conditions which minimized the racemization of Boc-*im*-benzyl-L-histidine,[9] led to virtual complete racemization of this residue. Approximately equal amounts of the 6-β-(pyridyl-2)-L-alanine and 6-β-(pyridyl-2)-D-alanine analogs were formed and were separated by chromatography on Sephadex G-25 using *sec*-butanol-3% NH_4OH (100:44). The individual diasteriomeric peptides were further purified by ammonium acetate gradient elution from carboxymethylcellulose (CM-25), until homogenous to tlc and electrophoresis at pH 1.85. Acid hydrolysis followed by L-amino acid oxidase digestion and amino acid analyses served to identify the L- and D-amino acid-containing peptides. This unusual degree of racemization is apparently related to the presence of the basic pyridine nitrogen atom adjacent to the amino acid side chain. The [6-β-(pyridyl-2)-D-alanine] analog was essentially inactive (0.1%) in the rat pressor assay.

The 8-Phenylalanine Position

Aromatic analogs of the 8-phenylalanine residue have shown pressor activities which may be related to the lipophilic character of their side chains. The 8-tyrosine residue is apparently too hydrophilic (83%,[10] 10%[4]), while the 8-*p*-bromophenylalanine residue may be too lipophilic (50%).[11] The lower aliphatic analogs [5-isoleucine,8-alanine]-angiotensin II[3],[12] and [1-asparagine,5-valine, 8-alanine]-antiotensin II[13] and the lower alicyclic analogs [5-isoleucine,8-α-aminocyclopentanecarboxylic acid]-angiotensin II[14] and [5-isoleucine,8-α-aminocyclohexane-carboxylic acid]-angiotensin II[15] showed virtually no agonist properties, but were active as antagonists to angiotensin II. We have prepared analogs with increasing aliphatic lipophilic character in the 8-position in order to differentiate the aromatic *versus* lipophilic roles in the agonist and antagonist responses. The [8-leucine], [8-norleucine], and [8-α-aminoheptanoic acid] analogs showed increasing pressor activities with increasing side chain lipophilic character: 1.0%, 6%, and 10%, respectively. When administered in a single dose concurrently with a single dose of angiotensin II, these 8-position aliphatic analogs showed additive pressor effects.

[1-Asparagine,5-isoleucine,8-leucine]-angiotensin II, when perfused at minimal pressor levels of 37.5 and 75 picomol/min, significantly reduced the pressor responses to single injections of 2, 4, and 8 picomol of [1-asparagine, 5-valine]-angiotensin II (Figure 1). In order to enhance

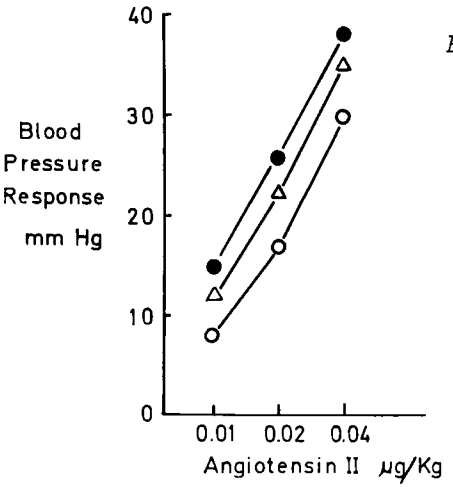

Figure 1: Antagonism to the rat pressure response to angiotensin II during infusion of [Asn^1,Ile^5, Leu^8]-angiotensin II. ●Control; Δ[Leu^8] analog 0.2 μg/kg/min; o [Leu^8] analog 0.4 μg/kg/min.

and prolong this antagonistic effect, we have prepared [1-sarcosine,5-isoleucine,8-leucine]-angiotensin II, an analog potentially resistant to aminopeptidase degradation.*

A single 400 picomol injection in a 180 gm male rat of the [Sar^1,Leu^8] analog produced a significant inhibition of the pressor responses to single doses of 3, 6, and 12 picomol of angiotensin II, given during a 45 min period after administration of the antagonist (Figure 2).

Infusion of angiotensin II at a rate of 70 picomol/min over 90 min produced a stable rat blood pressure which was 60 mm Hg higher than normal (Figure 3). Concomitant infusion of the [Sar^1,Leu^8] analog at a rate of 1400 picomol/min (20/1 molar ratio) produced a 50% fall in blood pressure within 3 min and a further decrease to a total of 67% during 30 min of infusion. When infusion of the [Sar^1, Leu^8] analog was stopped, but that of angiotensin II continued, blood pressure rose during 20 min, but was still depressed by about 40% relative to the control value. Blood pressure rapidly fell to a level close to that of

*After completion of this work we learned of a report of the long-lasting inhibitory properties of this compound.[16]

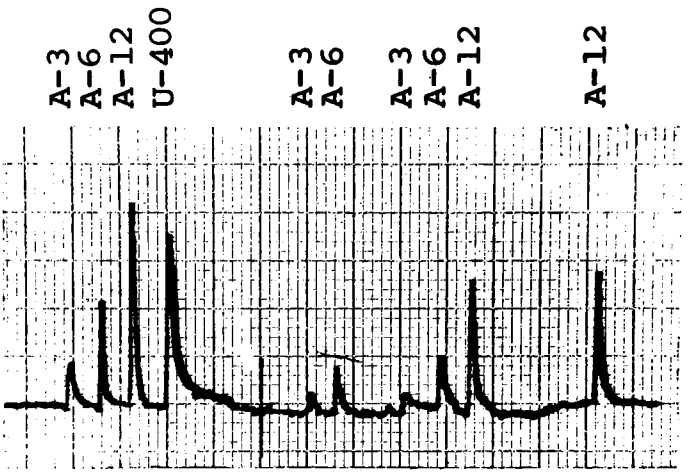

Figure 2: Record of rat pressure response to [Asn^1,Ile^5]-angiotensin II (A, x 10^{-12}mol), before and after administration of 400 picomol of [Sar^1,Ile^5,Leu^8]-angiotensin II (U, x 10^{-12}mol). Heavy lines equal 5 min.

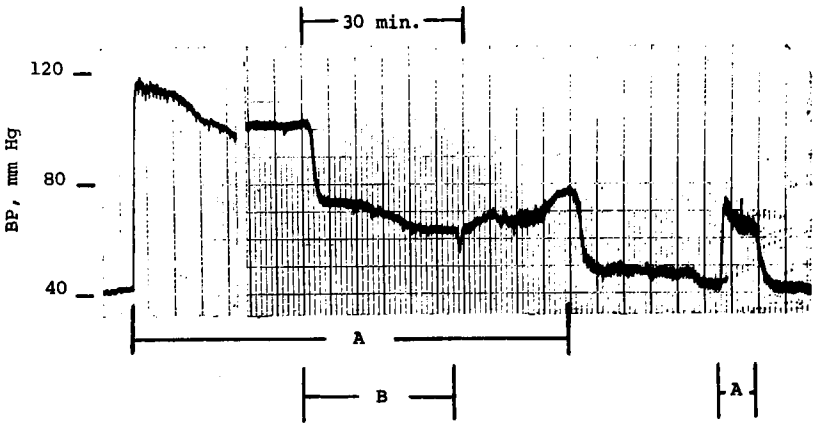

Figure 3: Record of rat pressure response to infusion of [Asn^1,Ile^5]-angiotensin II (A, 70 x 10^{-12}mol/min) and to [Sar^1,Ile^5,Leu^8]-angiotensin II (B, 1400 x 10^{-12}mol/min).

normal (40-50 mm Hg) when angiotensin II infusion was stopped during 25 min, then rose to about 40% of the normal response when infusion of angiotensin II was begun again, indicating the long lasting residual antagonistic effect of the infused [Sar^1,Leu^8] analog.

In conclusion, specific properties of side chains have been related to the pressor effects of angiotensin II. In the 5-position, the favorable effect of β-branching is present in side chains widely varying in polarity, except that a free hydroxyl group is detrimental.

The high dipolar character of an N-heterocyclic ring system, and presence of a tautomeric form which places a pyrrole-like NH group adjacent to the amino acid side chain, appear to be characteristics for maximal pressor response in the 6-histidine position.

In the 8-position, the lipophilic character of the unsubstituted phenylalanine aromatic ring is associated with maximal pressor response, although higher aliphatic residues also produce moderately active analogs. Aliphatic or alicyclic residues of low molecular weight are ineffective as agonists, but are effective as antagonists to angiotensin II.

Acknowledgments

This investigation was supported in part by Research Grant AM 08066 from the National Institute of Arthritis and Metabolic Diseases, and by Research Funds of the University of California Academic Senate Committee on Research. We thank Dr. S. R. Rapaka for preliminary studies on the synthesis of [Asn^1,Thr^5]-angiotensin II.

CHEMISTRY AND BIOLOGY OF PEPTIDES

PROPERTIES OF ANGIOTENSIN RECEPTORS IN SMOOTH MUSCLE: A PROPOSED MODEL

John Morrow Stewart, Richard J. Freer. Department of Biochemistry, University of Colorado School of Medicine, Denver, Colorado 80220

DATA FROM EXPERIMENTS ON the effects of changes in pH and Ca^{++} concentration on the response of smooth muscles to angiotensin II, (A II) from a study of the effect of amino acid substitutions at position 6 in A II and results of experiments with alkylating (affinity labeled) peptide derivatives have been combined to provide the basis for a hypothetical model of the topography of the A II receptor of smooth muscle, and to suggest a mechanism for the production of tachyphylaxis at low pH and Ca^{++} concentration.

The response of rat uterus to A II in low Ca^{++} (0.18 m*M*) de Jalon's solution is maximal at pH 8.0, and decreases at higher and lower pH. The decreased activity is most marked below pH 7, due to the production of a rapid and severe tachphylaxis. This observation suggested that the tachyphylaxis might be due to protonation of the imidazole of the histidine residue (pK 6.8). A series of 6-substituted analogs of A II was synthesized and assayed to test this hypothesis.[1] These [Asp^1, Ile^5]-angistensins II contained thienylalanine, phenylalanine, methionine, leucine, ornithine, arginine, or glutamic acid in position 6. In addition, [Asp^1, Val^5, pyrazolylalanine^6]-angiotensin II, a gift of Dr. Klaus Hofmann, was tested. The results showed that for maximum A II activity the side chain at position 6 must have both aromatic and nucleophilic character, and that when a strongly basic residue was present in this position, production of tachyphylaxis was severe.[2] In contrast to the earlier work of Rocha e Silva on histamine,[3] these data

suggest that the response is determined by protonation of the imidazole in the hormone, rather than in the receptor.

Development of tachyphylaxis to A II in rat uterus was dependent not only on pH of the medium but also on Ca^{++} concentration. When the concentration of Ca^{++} was 1.0 m*M*, tachyphylaxis was never seen at any pH. Recovery from tachyphylaxis in low pH, low Ca^{++} medium was very slow, requiring about one hour. However, the recovery could be greatly accelerated by raising either the pH or the Ca^{++} concentration of the medium. Guinea pig ileum responds to changes in pH and $[Ca^{++}]$ in a similar but less clear-cut manner.

Two peptides containing the nitrogen mustard chlorambucil (Chl) (*p*-[*N*,*N*-bis(2-chloroethyl)amino]phenylbutyric acid) were used to provide additional information about the A II receptor. [Chl^1]-A II specifically and irreversibly inhibited the action of A II on isolated guinea pig ileum, without affecting the response of the tissue to bradykinin, histamine, or ions.[4] This result suggests that the nitrogen mustard moiety of the hormone derivative is alkylating an anionic site on the receptor which normally combines with the guanidinium side chain of the Arg^2-residue. Chl-Pro-Phe-Arg^5 also produces a permanent inhibition of the response of ileum to A II, but this inhibition is quite different from that produced by [Chl^1]-A II. After treatment of the tissue with the larger derivative, no amount of A II could produce a maximal response, but after treatment with the small derivative, the dose response curves obtained had the characteristics of competitive inhibition; that is, the dose response curve was parallel to and displaced to the right of the control curve. A maximal response could always be obtained by large doses of A II. However, after washing, the inhibition returned. A suggestion for this type of inhibition[6] is that the inhibitor is bound to the tissue by alkylation of an anionic site not directly on the receptor, but adjacent to it, so that the receptor is partially occluded. High concentrations of A II would displace that part of the derivative which lay directly over the receptor, and allow a full response. Since the derivative is covalently attached to the tissue, once the high concentration of A II was washed out the peptide part of the inhibitor would return to occlude the receptor.

Figure 1 depicts schematically the structure of A II, showing those functional groups which are known to be important for biological activity. In the adjacent rectangle are suggested functional groups on the receptor which could

Figure 1

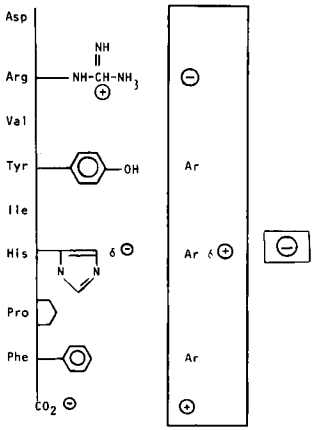

Figure 2

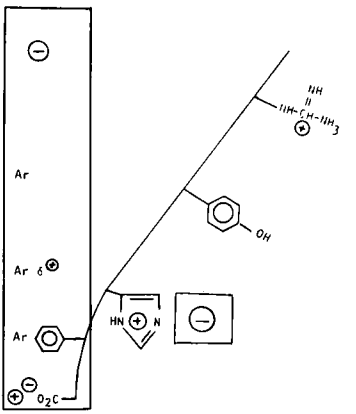

Figure 1: Suggested normal angiotensin-receptor interaction. The receptor area is indicated by the large vertical rectangle. The anionic site to the right of the receptor is normally occupied by Ca^{++}.

Figure 2: Suggested angiotensin-receptor interaction in tachyphylaxis.

most logically interact with the important groups on the peptide. The anionic site on the receptor adjacent to the locus of combination with the histidine of A II is probably normally occupied by Ca^{++}. Figure 2 depicts a suggested peptide-receptor interaction in tachyphylaxis. In low Ca^{++} medium, the anionic site would no longer be saturated with Ca^{++}, and would be available to combine strongly with the protonated form of the imidazole to anchor the peptide firmly to the receptor in an abnormal way. This would prevent normal agonist action of the adsorbed peptide, and would also inhibit entry of additional agonist to the receptor. The anionic site indicated at the top of the receptor model normally interacts with the guanidinium of the arginine residue, and may be the site alkylated by [Chl[1]]-A II. Further experiments are under way to seek additional confirmation of this receptor model.

CHEMISTRY AND BIOLOGY OF PEPTIDES

MODE OF ACTION OF PEPTIDE INHIBITORS OF ANGIOTENSIN-CONVERTING ENZYME.-I.-

M. A. Ondetti, J. Pluščec, E. R. Weaver, N. Williams, E. F. Sabo, O. Kocy. The Squibb Institute for Medical Research, New Brunswick, New Jersey 08903

FERREIRA *ET AL.*[1] DESCRIBED IN 1970 the isolation from the venom of *Bothrops jararaca* of several peptides capable of potentiating the biological activities of bradykinin and inhibiting the conversion of angiotensin I to angiotensin II. The sequence of one of these peptides was shown to be: <Glu-Lys-Trp-Ala-Pro (BPP_{5a}). Our work on the isolation of inhibitors of angiotensin-converting enzyme from the same venom led to the isolation and synthesis of six nona- to tridecapeptides:[2] <Glu-Trp-Pro-Arg-Pro-Thr-Pro-Gln-Ile-Pro-Pro (SQ 20,661); <Glu-Trp-Pro-Arg-Pro-Gln-Ile-Pro-Pro (SQ 20,881); <Glu-Asn-Trp-Pro-Arg-Pro-Gln-Ile-Pro-Pro (SQ 20,861); <Glu-Asn-Trp-Pro-His-Pro-Gln-Ile-Pro-Pro (SQ 20,858); <Glu-Ser-Trp-Pro-Gly-Pro-Asn-Ile-Pro-Pro (SQ 20,857); <Glu-Gly-Gly-Trp-Pro-Arg-Pro-Gly-Pro-Glu-Ile-Pro-Pro (SQ 20,718).

The studies of Cushman and Cheung[3,4] on the inhibition of isolated angiotensin-converting enzyme with the pentapeptide BPP_{5a} and longer-chain inhibitors, showed two important differences between these two groups of inhibitors: a) BPP_{5a} is (on a molar basis) at least ten times more active than the longer chain inhibitors; and b) the inhibitory activity of BPP_{5a} is destroyed rapidly when the pentapeptide is incubated with the converting enzyme in the absence of substrate and chloride ions. Under the same conditions, the inhibitory activity of the longer chain peptides is completely stable.

These two observations led us to undertake the synthesis of a number of analogs and derivatives of the pentapeptide BPP_{5a} with the aim of clarifying its mode of action and the cause of the instability of its inhibitory activity.

Synthesis

The strategy of stepwise condensation, starting from the C-terminal amino acid was employed for the synthesis of all peptides described in Table I. In a large number of cases, the C-terminal amino acid moiety was bound to an insoluble polystyrene divinylbenzene copolymer and the synthesis was carried out according to the solid-phase technique developed by Merrifield.[5] The *t*-butyloxycarbonyl group was utilized to protect the α-amino function of all amino acids, except pyroglutamic acid, and the benzyloxycarbonyl group to protect the ε-amino function of lysine. Dicyclohexylcarbodiimide was used for all the coupling steps, except in the cases of lysine and glutamine, for which *p*-nitrophenyl esters were employed. The removal of the butyloxycarbonyl group was achieved with *N* hydrogen chloride in acetic acid, and the removal of the peptide from the resin was carried out with hydrogen bromide in acetic acid. This latter procedure led to incomplete removal of the benzyl ester from the γ-carboxyl of glutamic acid in peptide 8, and hydrogenolysis was needed to carry this deprotection to completion.

The synthesis of the *t*-butyloxycarbonyl derivative of 3-L-amino-4-phenylbutyric acid (β-homophenylalanine) required for the solid-phase synthesis of peptide 20 was carried out by the Arndt-Eistert procedure, starting with *t*-butyloxycarbonyl-L-phenylalanine isobutylcarbonate mixed anhydride:[6]

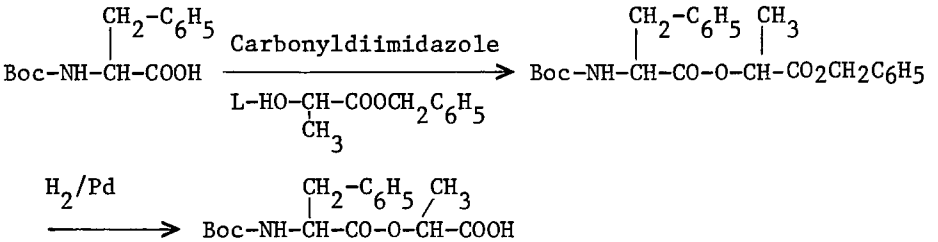
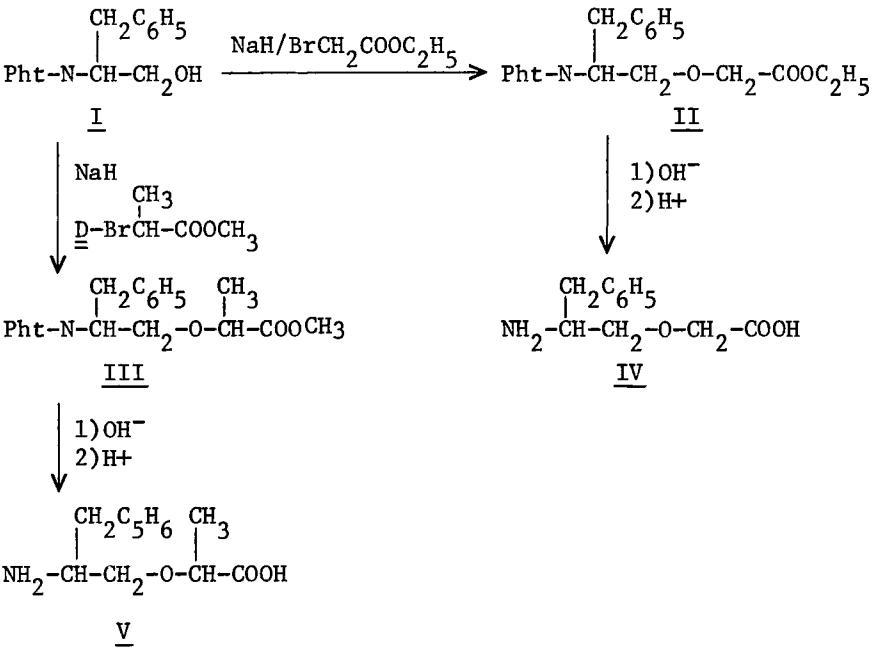
The intermediate diazoketone and methyl ester, and the final product, *t*-butyloxycarbonyl-L-β-homophenylalanine, were isolated in crystalline form, with good yields. The synthesis of this derivative by a similar procedure has been described recently.[7]

The synthesis of the depsipeptide 17 (Table I) by the solid-phase technique followed the approach described by Gisin *et al.* for the synthesis of valinomycin.[8] moiety was synthesized in solution:



Synthesis of the amino acid ether moieties required for the synthesis of peptides 18 and 19 proceeded as follows:



The amino acid ether IV was obtained in crystalline form, but all attempts to crystallize V were unsuccessful. Both compounds showed the expected IR and NMR spectra. The corresponding *t*-butyloxycarbonyl derivatives were obtained as oils, and were purified by countercurrent distribution or through crystallization of the corresponding dicyclohexylamine salts. The configuration of the asymmetric carbon atom in the "lactyl" moiety of V is expected to be L, assuming a 100% inversion in the reaction from I to III.

In some of the peptides of Table I, the strategy of stepwise condensation was carried out in solution, starting from a benzyl ester of the C-terminal amino acid, and utilizing the active ester procedure for all coupling steps. The synthesis of peptide 15 was also carried out in the stepwise manner, starting with pyrolidine.

Structure-Activity Relationships

How the replacement of amino acids effected the inhibitory activity of BPP_{5a} on the angiotensin-converting enzyme can be summarized as follows:

a) The pyroglutamyl residue in position 1 can be replaced by an alicylic carboxylic acid of similar size without any loss of activity. Bulky alkyloxycarbonyl acyl groups are considerably less efficient in this respect (peptides 2, 3, 4, and 5, Table I).

b) The side chain amino function of the lysine residue in position 2, is not essential for the inhibitory activity (peptides 6 and 7). However, it cannot be replaced by a carboxyl function (peptide 8) nor can the aliphatic chain be shortened significantly (compare peptides 9 and 10) without considerable loss of inhibitory potency.

c) An aromatic amino acid is the best choice for position 3 (peptide 1). Replacement of tryptophan with aliphatic acyclic amino acid or cyclic amino acid residues lowers the inhibitory activity (peptides 10 and 11) and the reduction in activity is even greater if hydrophilic functional groups are present in the side chain (peptide 12).

d) The replacement of the alanine residues in position 4 by a proline residue diminishes the inhibitory activity drastically (peptide 14). However, this inhibitory activity remains unaltered when this peptide 14 is incubated with the converting enzyme in the conditions described in the introduction, as is the case with the longer-chain peptidic inhibitors that have the C-terminal sequence Ile-Pro-Pro.

e) Elimination of the carboxyl group from the C-terminal amino acid moiety of BPP_{5a} destroys the inhibitory activity completely (peptide 15).

The structure-activity relationships described above parallel rather closely the requirements for substrate specificity of the converting enzyme,[10] and support the hypothesis advanced by Cushman and Cheung[4] that BPP_{5a} interacts with the enzyme at the active site, and is, under certain conditions, cleaved at the Trp-Ala bond by the converting enzyme itself.

Since substitution of Pro for Ala (peptide 14, Table I) gives inhibitors that are stable, but of decreased potency, other modifications of this bond were attempted:

1) Replacement of L-Trp by D-Trp (peptide 16);
2) Change from an amide to an ether bond (peptides 18 and 19);
3) Replacement of alanine by lactic acid (peptide 17); and
4) Substitution of β-homophenylalanine for tryptophan (peptide 20).

Only the last two modifications yielded inhibitors with potency comparable to that of BPP_{5a}. The inhibitory activity of the depsipeptide 17 was destroyed rapidly by the converting enzyme, but that of the homopeptide 20 remained unaltered under the same conditions.

Acknowledgment

The authors thank Dr. D. Cushman and Mr. H. S. Cheung for the assays of inhibition of the angiotensin-converting enzyme, and for the stimulating exchange of ideas.

CHEMISTRY AND BIOLOGY OF PEPTIDES

ISOTOPE DERIVATIVE ASSAY OF NANOGRAM QUANTITIES OF ANGIOTENSIN I: USE FOR RENIN MEASUREMENT IN PLASMA

Robert I. Gregerman, Mary Ann Kowatch. Gerontology Research Center, National Institute of Child Health and Human Development, National Institutes of Health, Baltimore City Hospitals, Baltimore, Maryland 21224

WE HAVE PREVIOUSLY DESCRIBED a double isotope derivative method for the quantitation of nanogram amounts of angiotensin II and some related peptides.[1] Subsequently we reported an assay of human renin by a procedure which uses this method for quantitation of angiotensin I generated by the action of the enzyme on an excess of hog renin substrate.[2] This technique has now been standardized for the assay of renin in human plasma.

Figure 1 shows a general scheme for the double isotope quantitation of peptides. The principles involved follow those which have been used extensively in the field of steroid analysis. Derivatization of the peptide is performed with labeled reagent of one isotope while recovery is corrected by use of an indicator amount of the compound (or its derivative) which contains a second isotope. Varying degrees of purification of the derivatized product are accomplished by whatever means prove necessary and convenient for the particular application. In the following description italicized numbers refer to Figure 1. For the angiotensins we use tritium-labeled 1-fluoro-2,4-dinitrobenzene (^{3}H-FDNB) *1* to derivatize the peptides to the dinitrophenyl (Dnp) derivatives. ^{14}C-Dnp-angiotensin I, prepared separately, is used to monitor recovery *2* and carrier Dnp-angiotensin I is added after derivatization *4*. Thin layer chromatography *5* is used for purification of the product after removal of excess ^{3}H-FDNB *3*. In our

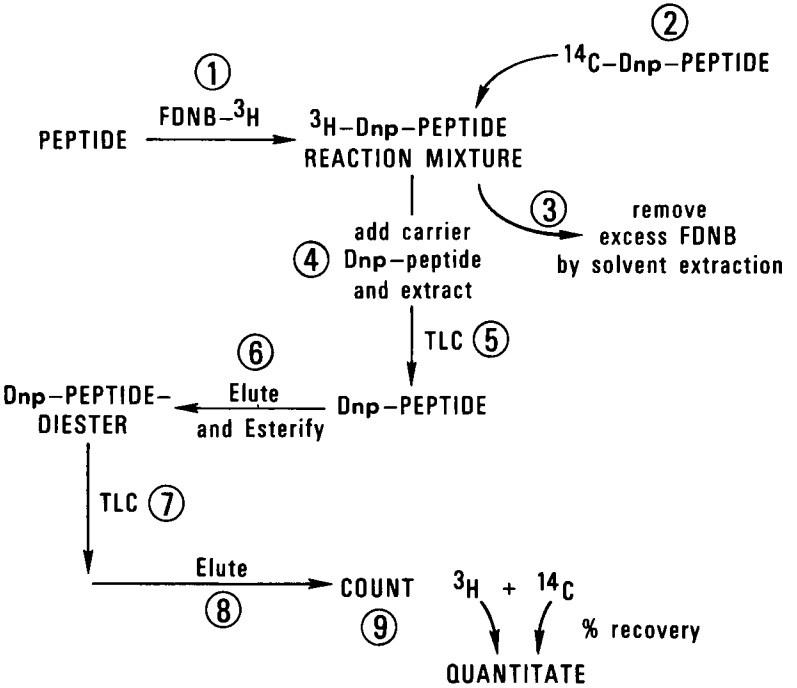

Figure 1: General scheme for the double isotope derivative assay of peptides

procedure each tlc step is performed in two dimensions. After the first tlc the Dnp-angiotensin I is eluted and simultaneously further derivatized *6* to the dimethyl ester before the repeated tlc. The extent of this purification is determined primarily by our need for a low reagent and plasma blank in order to measure low levels of renin in human plasma. For some applications only a single tlc step might be sufficient while for others, in which complex mixtures of peptides were involved, additional purification might be required.

After derivatization with FDNB, angiotensin I contains 4 Dnp groups: Dnp-Asp-Arg-Val-Tyr(Dnp)-Ile-His(Dnp)-Pro-Phe-His(Dnp)-Leu. The four sites which are derivatized are the N-terminal NH_2 of Asp, the two imidazoles of His and the phenolic hydroxyl of Tyr. This stable derivative is, of course, yellow. More importantly, it is strongly UV-absorbing, which allows non-destructive localization on

tlc. The tritium-labeled reagent is also stable and relatively inexpensive. Details of the chemical manipulations have been published previously.[1,2]

The scheme for preparation of the plasma for renin assay and isolation of generated angiotensin I from the plasma incubation mixture is shown in Figure 2. Passage of a

1. PLASMA (EDTA) THRU DOWEX 50-X8
2. ADD SUBSTRATE, BUFFER, PMA
3. INCUBATE
4. PASS THRU DOWEX 50-X8
5. WASH WITH WATER
6. ELUTE WITH 2 M PYRIDINE
7. CONCENTRATE TO DRYNESS

Figure 2: Plasma handling for renin assay by double isotope derivative assay: preparation of plasma, incubation, and isolation of generated angiotensin I

2 ml plasma sample through a 1 ml Dowex bed removes any preformed angiotensin I and a number of materials which would otherwise react with the ^{3}H-FDNB reagent and so interfere with the procedure. An 0.5 ml sample of the "cleaned" plasma is then incubated with excess hog substrate in the presence of EDTA at pH 7.6. Phenylmercuric acetate (PMA) is used as a bacteriostat. These conditions are essentially those of Gould *et al.*,[3] except that in our procedure the EDTA concentration is high enough (0.03 *M*) to inhibit converting enzyme as well as angiotensinases. Angiotensin standards and renin (plus hog substrate) standards are run with each assay. After completion of incubation for 18 hours the plasma mixture is passed through a 1 ml Dowex bed in a disposable syringe barrel. This adsorbs the generated angiotensin I, and eliminates the bulk of the protein and salts. The angiotensin I is then eluted with pyridine directly into the derivatization tube, evaporated under an air stream, and derivatized.

As reported earlier, 1 x 10^{-4} Goldblatt unit (GU) of human renin yields approximately 100 ng of angiotensin I in 18 hours under these conditions.[2] The recovery of 1 x 10^{-4} GU of renin added per ml was 87.7 ± 8.7% (S.D.) for 24 determinations made over about 18 months. Thus, the mean recovery is close to 90%, but some samples do appear to have some residual angiotensinase activity.

Renin assays have been made by the double isotope derivative method applied to plasma from approximately 20

normal human subjects on normal and high sodium intakes. The recumbent values have a mean of about 0.2×10^{-4} GU/ml and approximate those reported in the literature using similar incubation conditions and bioassay. Upright values and post diuretic values (4 hr after 80 mg furosemide given orally) increase about as expected to approximately 0.35 and 0.6×10^{-4} GU/ml respectively. Values for pregnant subjects are greatly elevated (mean about 1.2×10^{-4} GU/ml) but perhaps somewhat less so than one might have expected.[3] Our seven anephric subjects (3 males, 4 females), whose kidneys had been removed prior to anticipated kidney transplants, all had measurable renin with values very close to those of the normal recumbent subjects.

The literature is conflicting on the issue of whether or not the plasma of anephric subjects contains measurable renin. A number of workers using bioassay methods have reported low normal or normal values[4] while recently both a bioassay method and radio-immunoassay technique were said to show no detectable renin.[5] If one takes the view that our method measures material other than angiotensin I, *i.e.*, that the anephric plasmas represent the biological "blank" for our method, then one must conclude that, since recumbent normal subjects have the same values, that they too have no detectable renin. We do not favor such an interpretation and at present take the view that anephric subjects have low but measurable rates of angiotensin generation. This point is under further investigation.

We have compared the results by our isotope derivative method on individual samples with those obtained by bioassay of the same samples performed in Dr. Gould's laboratory. The comparison shows a reasonable but by no means perfect correlation of the values.

This application of the double isotope approach to peptide quantitation suggests to us that, even though techniques such as radio-immunoassay (angiotensin I) may be more convenient for routine use, and therefore preferable for renin measurement, the double isotope method may well be useful under special circumstances and for the quantitation of other peptides of biological interest.

ON THE IDENTITY OF PEPSITENSIN

T. B. Paiva, A. Grandino, M. E. Miyamoto, A. C. M. Paiva. Department of Biophysics and Physiology, Escola Paulista de Medicina, 04023, São Paulo, S.P., Brazil

PEPSITENSIN, A VASOPRESSOR PEPTIDE obtained by peptic proteolysis of a plasma substrate, has biological activities that are qualitatively identical with those of angiotensin II,[1] but the two peptides were shown to be different.[2] Two different amino acid sequences have been proposed for this peptide: Franze *et al.*[3] isolated [Val^5]-angiotensin I (AI) from ox plasma incubated with pepsin at pH 6 and Hochstrasser *et al.*[4] proposed the sequence Asp-Arg-Val-Tyr-Val-His-Pro-Phe-His-Leu-Leu ([Val^5]-AI-Leu) for a pepsitensin obtained from peptic proteolysis of ox plasma at pH 3. These results would suggest that pepsin acts at a different peptide bond in plasma renin-substrate, according to the pH of incubation (Figure 1). In order to verify this hypothesis we have synthesized the following peptides: (*1*) [Val^5]-AI-Leu; (*2*) [Ile^5]-AI-Leu; (*3*) Val-Tyr-Ser; (*4*) Leu-Val-Tyr-Ser; (*5*) His-Leu-Leu-Val-Tyr-Ser. Merrifield's solid phase method was employed[5] with some modifications.[6] The activity of compounds *1* and *2* on the rat's blood pressure was, respectively, 1.28(±0.08)% and 1.42(±0.09)%, relative to angiotensin II. Compounds *1* and *2* were easily converted to fully active angiotensin II by the action of carboxypeptidase A.

Peptides *2* - *5*, [Ile^5]-angiotensin I and [Ile^5]-angiotensin II were compared with the products of peptic hydrolysis of synthetic [Ile^5]-tetradecapeptide renin substrate (Schwarz/Mann) done at pH 3.0 and at pH 6.0. At both pHs, the main products were angiotensin I and *4*,

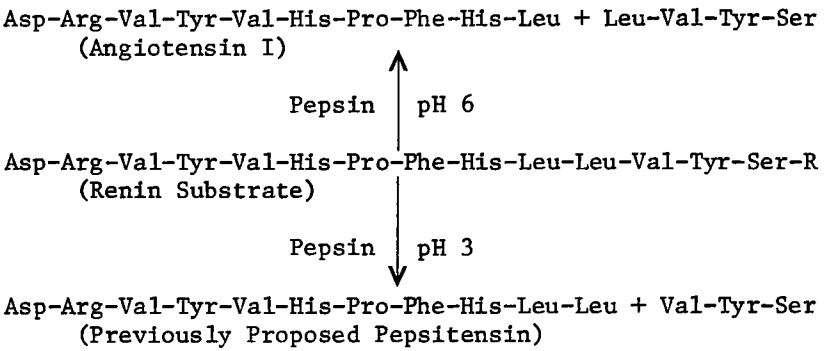

Figure 1: Hypothetical production of two different "pepsitensins" by peptic hydrolysis of renin substrate at pH 3 and at pH 6.

shown by high voltage paper electrophoresis and tlc with three solvent systems. *2* and *3* were not detected as products of peptic hydrolysis at either pH. This indicates that there is only one pepsitensin, which is identical with angiotensin I.

CHEMISTRY AND BIOLOGY OF PEPTIDES

BIO-ISOSTERES OF A PEPTIDE RENIN INHIBITOR

M. J. Parry, A. B. Russell, M. Szelke. Research Division, Pfizer Ltd., Sandwich, Kent, England

IT WAS REPORTED BY KOKUBU and coworkers[1] in 1968 that the tetrapeptide ester H-Leu-Leu-Val-Phe-OMe *1* was a competitive *in vitro* inhibitor of rabbit renin, and that it lacked hypotensive activity in rats. It was also shown[1] that the Leu^1-Leu^2 grouping and an aromatic amino acid residue at position 4 were essential for renin inhibitory activity and that even conservative replacements of Leu, as in H-Ile-Leu-Val-Phe-OMe *2* or H-Val-Leu-Val-Phe-OMe *3* produced inactive compounds.

In the course of our investigations concerned with the role of the renin-angiotensin system in hypertension we found that *1* did not inhibit endogenous renin in rat plasma, probably as a result of enzymatic breakdown and binding to plasma proteins. Subsequently, we undertook various chemical modifications of *1* with the aim of obtaining a renin inhibitor also effective *in vivo* and therefore of practical value in assessing the pathogenetic role of renin in experimental hypertension.

In view of the specific structural requirements with regard to the side-chains in *1*, these were retained during modification. In order to increase stability towards proteolytic enzymes, some or all of the α-amino acid units in *1* were replaced by the isosteric "reduced" units -NH-HCR-CH_2- or carbazic acid units -NH-NR-CO- bearing the side-chain R of the amino acid residue that they replace.

In an *in vitro* assay system based on the radioimmunoassay of angiotensin-I liberated by pig renin from synthetic tetradecapeptide substrate, several of the resulting modified

peptides, *e.g.* *4* - *7* (Figure 1) were found to be specific inhibitors of renin with a potency equal or superior to that of the parent tetrapeptide ester *1*.

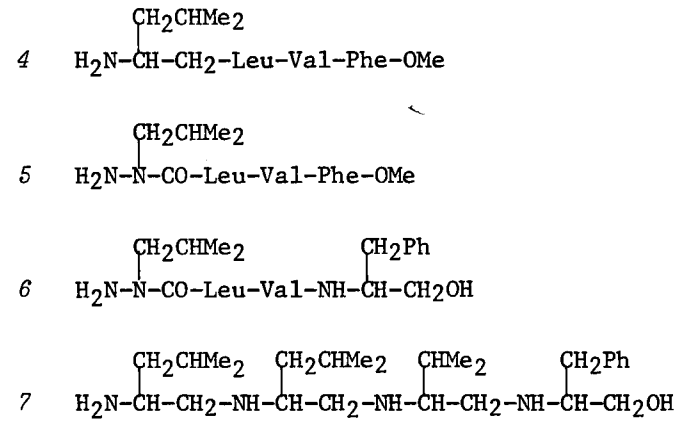

Figure 1: Bio-isosteres of peptide renin inhibitor, H-Leu-Leu-Val-Phe-OMe

Moreover, *4* and to a lesser degree *5* and *6* inhibited the liberation of angiotensin-I from plasma substrate by endogenous renin in rat plasma whereas the parent peptide *1* was completely inactive in this system (see Table I).

The modified peptides *4* - *7* were completely stable in the presence of leucine aminopeptidase while under the same conditions *1* was rapidly hydrolysed to the component amino acids.

In a group of 3 rats, made hypertensive by unilateral renal artery constriction, the partially reduced peptide *4* caused significant falls in blood pressure on each of 3 days when administered daily at 10 mg/kg, as compared with a control group given saline injections. Initially there was a short-lived rise in blood pressure of 5 mm, followed after 2 hours by a fall lasting several hours and reaching a maximum of 25 mm after 5 hours, which represents an antihypertensive effect of approx. 33% (*i.e.* *4* abolished one third of the rise in blood pressure caused by constriction of the renal artery). At higher doses (*e.g.* 20 mg/kg), *4* elicited acute cardiovascular effects (bradycardia, hypotension) and was not investigated further.

Table I

Inhibition of Renin *in vitro* by Compounds *1 - 7*

Compound	*% Inhibition*		
	of pig renin cleaving synthetic substrate in pH 6 phosphate buffer		*of endogenous renin cleaving natural substrate in rat plasma at* $10^{-3}M$
	at $10^{-3}M$	*at* $10^{-4}M$	
1	56	10	0
2	0	-	-
3	0	-	-
4	-	34	84
5	-	28	6
6	-	22	7
7	29	-	-

Modified peptides *4 - 7* were synthesized as follows:
(a) Reduced analogues. Compound *4* was obtained *via* the reductive alkylation of tripeptide ester *9* with the protected α-aminoaldehyde *8*, the latter being prepared by Pfitzner-Moffatt oxidation[2] from *N*-tosyl leucinol (Figure 2).

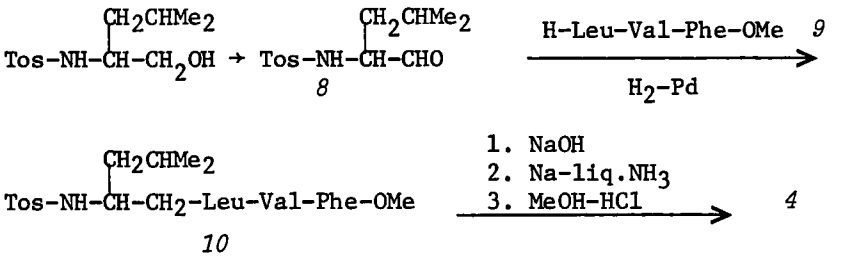

Figure 2: Synthesis of reduced analogue[4] of peptide renin inhibitor, H-Leu-Leu-Val-Phe-OMe.

Compound *6* containing a reduced C-terminal residue was prepared from the corresponding peptide ester by reduction[3] with $NaBH_4$. The totally reduced peptide *7* was obtained *via* reduction of *1* with $LiAlH_4$ in refluxing tetrahydrofuran.[4,5]

(b) Aza-peptides *5* and *6*, in which the Leu^1 residue is replaced by the isosteric carbazic acid, were synthesized *via* condensation of the protected carbazyl chloride *11*[6] with the peptide ester *9* (Figure 3).

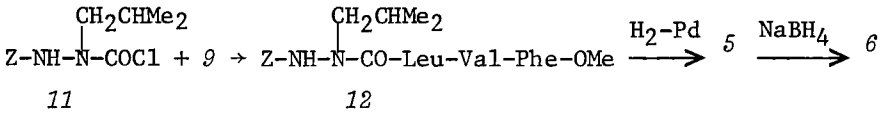

Figure 3: Synthesis of aza-analogues of peptide renin inhibitor, H-Leu-Leu-Val-Phe-OMe.

CHEMISTRY AND BIOLOGY OF PEPTIDES

SOME RECENT DATA ON ANGIOTENSINAMIDE II CONFORMATIONS

S. Fermandjian, D. Greff, P. Fromageot. Service Biochimie, Département Biologie, Centre d'Etudes Nucléaires de Saclay, 91 Gif sur Yvette, France

SUMMARY--The characteristics of Angiotensinamide II and some of its analogs have been investigated by a variety of techniques, under different environmental conditions. It is concluded that one deals with monodisperse angiotensinamide II only in dilute aqueous solution or in trifluoroethanol and hexafluoroisopropanol. In concentrated aqueous solution, or in DMSO, the peptide is aggregated. Data collected strongly indicate the tendency of the molecule to fold on itself. When this tendency is enhanced by organic solvents a large proportion of the peptide adopts a preferred overall conformation, defined as follows: a first turn takes place at the level of valine in position 3 and tyrosine in position 4. A second turn at the His-Pro linkage, corresponding to a histidine carbonyl group pointing approximately towards the same direction as the proline carbonyl group,* brings the phenylalanine side chain close to the valine side chains. This delineates a hydrophobic pocket on one side of the molecule. Arginine, tyrosine and histidine side chains remain free of interactions.

---

*To prevent misunderstanding about the His-Pro peptide nomenclature, we like to remind that we call "*cis*" that conformation in which the histidine carbonyl and the proline carbonyl are pointing to the same direction and "*trans*" the opposite.

THE RAPID AND SPECIFIC PHYSIOLOGICAL responses elicited by an intravenous injection of a variety of peptide and other hormones are still puzzling phenomena; the more so, when one considers the minute amounts of compounds introduced into the circulation. The importance of specific binding of biologically active molecules to specialized cellular sites was early postulated and firmly stated as for instance by von Buddenbrock[1] when he wrote: "Dem Biologen muss als Leitfaden dienen dass die chemische Konstitution nicht das letzte Wort ist. Das Entscheidende ist schliesslich das Reaktionssystem."

When labelled peptide hormones of sufficiently high specific radioactivity were obtained, the studies of their mode of action took a new turn. The target cells could be directly identified. Moreover, the existence of hormone-specific binding sites on the surface of such cells could be recognized and their affinity for the relevant hormones measured. It is gratifying to note that the binding constants measured are in agreement with the concentrations required to elicit a hormonal response. This progress prompted a vivid interest in conformational relationships between hormones and receptor sites. This is a continuation of the previous efforts to correlate hormone primary structure and biological activity. The underlying concept is that a peptide hormone has a preferred conformation in the prevailing environment which allows the first interaction with the specific binding site to take place. Following this the peptide environment suddenly changes, as well as that of the corresponding receptor site, and additional conformational changes are envisioned, leading to a tight binding and, conditions permitting, to a biological response.

In the following we shall discuss some conformational data concerning angiotensinamide II, an octapeptide of linear primary structure corresponding to Asn-Arg-Val-Tyr-Val-His-Pro-Phe, when of bovine origin. When extracted from horse or hog, valine in position 5 is replaced by isoleucine.[2]

Ideally, one should work out the conformation(s) of such a peptide under the condition prevailing in the vicinity of the receptor sites or *in situ*. As this is not feasible yet, one is left with the study of angiotensinamide II under circumstances which might be far from the physiological ones, but which should reveal the capacities of the molecule to adopt preferential conformations.

Infrared and Raman Spectroscopy

Between the vibration bands of peptide bonds and the structure of polypeptides, there exist empirical[3,4] as well as theoretical relations.[5] Good agreement has been found between IR spectral analyses according to Miyazawa's theory and peptide conformations in a variety of cases, for instance with hexa-L-alanine[6] and octabenzyl glutamate.[7] The problem was to identify the peptide vibration bands in the complex spectra given by a heteropeptide like angiotensinamide II. This was accomplished through comparison with the spectra recorded for the constituant amino-acids and for peptides of increasing size.[8] We thus found in the amide I region of IR spectra an intense band close to 1635cm^{-1} and a shoulder at 1685cm^{-1}. Their intensities relative to side chain bands decreased considerably when going from the octapeptide to the tetra and pentapeptides, suggesting that these bands corresponded to peptide bond vibrations, indeed. Their presence point to an antiparallel β structure as described for both short[9,10] and long polypeptide chains.[11,12] Moreover, Raman spectra showed two groups of bands between 1600 and 1700 cm^{-1}, which may contain bands at 1635, 1649, 1660, 1668 and 1689 cm^{-1}. The 1635, 1649 and 1689-1685 cm^{-1} bands correspond to the components of amide I bands according to Miyazawa's analysis of β structures, leaving open the interpretation of the 1660 and 1668 bands. Using Miyazawa's set of equations and ascribing $\nu(0.\pi)$ = 1685 cm^{-1}, $\nu(\pi.0)$ = 1635 cm^{-1} and $\nu(\pi.\pi)$ = 1649 cm^{-1}, one gets $\nu(0.0)$ = 1671 cm^{-1}. The latter, being a symetrical vibration should be IR inactive, but observed in Raman spectra and might well correspond to the 1668 cm^{-1} band. By the same computation ν_0 = 1660 cm^{-1}. These values allowed an estimation of the intrachain D_1, and interchain D_1' coupling terms. The values found D_1 = 18 cm^{-1} and D_1' = -7 cm^{-1} were of the expected signs and size for an antiparalled β conformation.

The 1660 cm^{-1} frequency, attributed to an amide group that is no longer subject to vibrational interactions, may correspond to an unordered fraction in the peptide studied. This assignment is based on several arguments: the 1660 cm^{-1} amide frequency is close to values deduced from IR spectra of nylon 66 and polyglycine, which are unordered polypeptides. The contribution of the 1660 cm^{-1} band increases in the peptide fragments 1-4 and 5-8 of angiotensin, whereas the 1685 cm^{-1} band decreases. The bands localized in the amide III region (1200-1350 cm^{-1}) also support the conclusion of a significant proportion of β conformation,

i.e. the 1236 and 1274 cm^{-1} bands observed on Raman spectra of angiotensinamide II are similar to those noted for pentaalanine[6] (1231, 1250 and 1268 cm^{-1}) for polyserine (1235 cm^{-1}) and for polyvaline (1231, 1276, 1291 cm^{-1}).[13] The bands localized in the amide II (1500-1550 cm^{-1}) and amide IV to VI regions (below 850 cm^{-1}) were not convincing and presently of little use.

The results obtained by Raman spectroscopy of concentrated angiotensinamide II solutions were in agreement with those reported for dry material. The multiplicity of bands in the amide I region, the shoulder at 1685 cm^{-1} as well as the frequencies of the amide III vibration bands indicated a high proportion of antiparallel β conformation as in the dry state. These results merely indicate that under conditions which promote inter or intra peptide interactions, an antiparallel β type of packing is more stable than other arrangements. What does antiparallelism stand for in the present case? IR or Raman studies did not shed light on the problem. Rayleigh diffusion measurements in concentrated (0.05*M* to 0.2*M*) aqueous solutions indicated that angiotensinamide II behaved as if it were a polymer of high molecular weight. Thus an intermolecular association takes place, by hydrogen bonding between antiparallel peptide chains. In addition, the double strands thus generated very likely aggregate thus mimicking the adsorption of free angiotensin on a variety of surfaces. The conclusions reached by IR spectroscopy on backbone conformation of solid angiotensinamide II are supported by circular dichroism measurements on dry angiotensin II films.[14] Reducing the concentration of aqueous solutions of angiotensinamide II diminishes the interpeptide interactions. Below 0.02*M* at pH 6, angiotensinamide II behaves as a monomer as shown by Rayleigh diffusion experiments,[15] by sedimentation equilibrium[16] and, at still lower concentration, by thin film dialysis.[17] Very interestingly, Printz, Williams and Craig[18] found at 0.003-0.006 *M* peptide concentration at least one and possibly two backbone peptide hydrogens of Val^5-angiotensinamide II to be involved in intramolecular hydrogen bonding in acidic aqueous medium. This suggests a folded conformation of the molecule. More evidence on the ability of angiotensinamide II to adopt preferred conformations was obtained by thin film dialysis[17] and gel filtration. Craig *et al.*[17] and de Fernandez *et al.*[19] studied the escape time of angiotensinamide II from thin films and observed two to four fold increases of T/2 with rising pH (from neutral to alkaline). These results

indicate change from a compact to an expanded state. Similarly, filtration of angiotensinamide II through Sephadex G-25 gave rise to either one or two peaks, depending on temperature, pH and ionic strength of the eluant.[20,21]

Circular Dichroism Studies

Circular dichroism spectra allow further insight into the conformational behavior of angiotensin II. Comparison of CD spectra of 0.5-1.1·10^{-3} *M* aqueous solutions (pH 6) of angiotensinamide II with those of analogs and lower homologs indicated that the hormone, the [4-phenylalanine] analog, as well as des-(8-phenylalanine)-angiotensinamide II exhibited certain degrees of organization whereas the shorter homologous peptides did not. On the other hand, the [5-isoleucine, 8-alanine] analog, under identical conditions gave a spectrum typical for an unordered conformation. These results show the conjugated importance of chain length and amino acid composition.

Interestingly enough, heating aqueous solutions of angiotensinamide II promoted an enhancement of the negative CD bands located at 224 and 237 nm, Figure 1. The molar

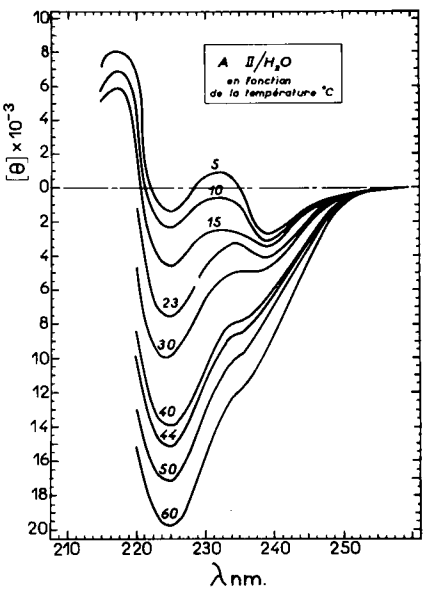

Figure 1: Circular dichroism spectra of angiotensinamide II in aqueous solution at different temperatures.[14]

ellipticity of the former changed from $[\Theta] = -4 \cdot 10^3$ at 15°C to $[\Theta] = -20 \cdot 10^3$ at 60°C suggesting an extensive organization of the molecule as the temperature was raised. No such dramatic changes were observed with the [5-isoleucine, 8-alanine] analog.[14] This temperature dependent folding might be a consequence of hydrophobic forces coming into play when the solute is more loosely solvated. The presence of the -Val-Tyr-Val- sequence and of phenylalanine seems to be of importance in this respect. Bringing these side chains together implies a folding of the molecule, around the tyrosine residue and a *cis* conformation of the His-Pro peptide linkage. As a matter of fact, the increase of ellipticity at 237 nm might well relate to the *cis* configuration of the His-Pro peptide bond as evidenced by the data of Legrand and Viennet[22] and those of Bovey and Hood.[23] In the absence of a terminal phenylalanine this mutual stabilization of the hydrophobic side chains would be less likely; this agrees with observed data. These results underline the importance of the surrounding medium and raise the questions (a) whether it is possible to enhance further the folding induced by a rise in temperature and (b) what is then the shape of the molecule?

A spectacular enhancement of angiotensinamide II folding is caused by organic solvents. Trifluoroethanol for instance promoted a sharpening of CD spectra leading to a more than twofold increase of [Θ] at 224 nm, Figure 2. The asymmetry

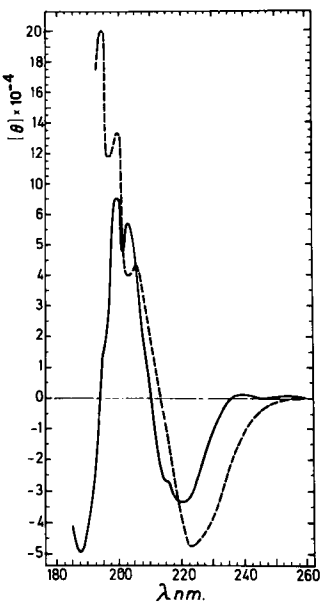

Figure 2: Circular dichroism spectra of angiotensinamide II dissolved in trifluoroethanol (-----) and of a dry film obtained from trifluoroethanol solution.

of that negative band toward the longer wave lengths suggests that the 237 nm negative band is also increased, both bands merging together. In addition positive bands become observable at 195, 198 and 205 nm. This profile is very similar to the predictions of Pysh[24] for antiparallel β conformations of peptide chromophores. We already know that in the dry state as well as in concentrated aqueous solutions, angiotensinamide II favors antiparallel β conformations. In more dilute aqueous solutions where angiotensinamide II is a monomer, we also know that a folded conformation is present, and in increasing concentrations as the temperature is raised. The situation in trifluoroethanol thus appears to be the limit of complete folding. As angiotensinamide II is not aggregated under these circumstances, antiparallel β conformation means a folding of the molecule on itself. Hydrophobic interactions, mentioned earlier, between the valine side chains represent probably one set of driving forces for a first β turn and the interactions of these valine side chains with the terminal phenylalanine side chain a second set of forces leading to another turn and together to the formation of a hydrophobic area on one side of the molecule. The roles of the different side chains of angiotensinamide II in stabilizing an overall conformation may be further studied by a variety of approaches. The availability of angiotensin analogs permitted the investigation of the influence of several amino acid substitutions. For this purpose CD spectra of various peptides dissolved in hexafluoroisopropanol were compared. This solvent was chosen for its intermediate properties between water and trifluoroethanol. Thus the subtle structural tendencies of the compounds investigated may express themselves in a more clear cut manner. First of all we examined the angiotensin II tripeptide fragment Val-Tyr-Val. It exhibits a positive band between 280 and 290 nm, Figure 3, due to the tyrosine side chain. On the other hand, angiotensinamide II shows no positive CD band between these wavelengths. Thus, the tyrosine environment in Val-Tyr-Val differs from that in angiotensinamide II. It should be pointed out that in angiotensinamide II the tyrosine side chain is free of interactions according to all available evidences.

Let us consider next [8-alanine]- and [8-isoleucine]-angiotensin II. Both give CD curves of similar shapes, different from that of the parent octapeptide, Figure 4. The [8-alanine] analog curve is reminiscent of the profile described for helical structure,[24] the more so when the

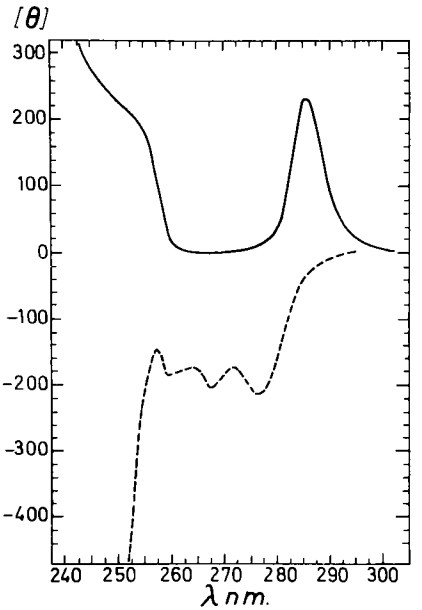

Figure 3: Circular dichroism spectra of Val-Tyr-Val (———) and angiotensinamide II (----) in hexafluoroisopropanol, in the range of 240-290 nm.

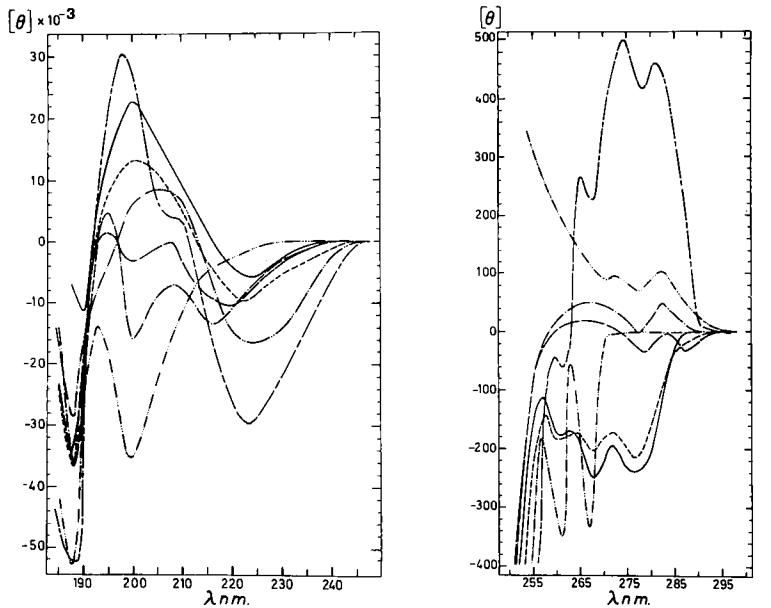

Figure 4: Circular dichroism spectra of angiotensinamide II and some analogs in hexafluoroisopropanol. A II (-----); [D-Arg^2]-A II (———); [Ile^8]-A II (———); [Pro^3]-A II (— — —); [Phe^4]-A II (— · · —); [D-His^6]-A II (— · · · —); [Ala^8]-A II (— · —).

solvent is trifluoroethanol. One should remain aware that CD curves may be misleading when no other information is available, as shown by Craig[25] for some cyclic antibiotic peptides. The [8-isoleucine] analog has less intense CD bands, intermediate between [8-alanine]-A II and angiotensin II. Both analogs point to the importance of the C-terminal amino acid. When the latter is removed, as in the (1-7)-heptapeptide, the CD curve in trifluoroethanol is similar to that of angiotensin II. When on the other hand alanine replaces phenylalanine, there is not only a lack of possible interactions with the valine side chains, but another type of association of alanine (carboxyl group ?) takes place, leading to a different folding of the whole peptide chain. The [8-isoleucine] analog seems to be subject to two opposite tendencies: one is that postulated for the [8-alanine] analog, the second may be a weak interaction between the 8-isoleucine side chain and the 3-valine side chain. The result is a larger flexibility. Both analogs are competitive inhibitors of angiotensinamide II,[26] but interestingly enough, the [8-isoleucine] analog is altogether a more potent inhibitor than [8-alanine]-A II and at high concentrations, possesses some agonistic activity. Thus the role of a hydrophobic side chain in position 8 seems to be important both for the stability of the conformation needed for binding as well as for the eventual triggering of the biological response.

Further precise information about the shape of the molecule may be gleaned from studies of CD curves. The [2-D-arginine] analog presented a curve nearly identical to that of angiotensinamide II suggesting that the side chain of arginine plays no noticeable role in maintaining the general conformation in solution. This side chain resides, therefore, on the surface of the molecule and can be inverted from L to D without interfering with the whole structure. This conclusion was supported when a cyclic derivative, obtained by condensation of the guanidine group of angiotensinamide II with cyclohexanedione, gave also a CD curve similar to that of the parent compound. The cyclic derivative exhibited nearly full pressor activity, whereas the [2-D-arginine] analog has almost none. Obviously the spatial positioning of the basic nitrogens of arginine is of importance for the biological response. These results suggest that the receptor groups which interact with these guanidine nitrogens are not embedded in a cleft as the imidazolidinone derivative has access to them.

The location of the imidazole ring of histidine in angiotensinamide II can be estimated by a similar approach.

Replacing L-histidine by D-histidine leads to a complete disorganization of the structure as indicated by CD spectra. Thus, as far as the conformation of angiotensinamide II in organic solution is concerned, this observation eliminates from consideration several possible locations for the L-histidine side chain and has to be remembered when building a model. The [3-proline] analog, on the other hand, does present CD curves which suggest a strong enhancement of the angiotensinamide II folded conformation; in addition, the tyrosine environment changes, as evidenced by the positive CD bands between 275 and 285 nm. That the rigidity introduced by the proline residue leads to a more folded conformation is in agreement with a β turn between the residues in positions 3 and 4. This [3-proline] analog possesses half the pressor potency of the parent hormone. This indicates, like the CD curves, that the general features of the molecule are not grossly modified. It shows merely a loss of flexibility for closer adjustment reflecting probably a restriction in the rotation of the tyrosine side chain. It may be appropriate to note that these substitutions of the third amino acid indicate its major importance for the conformation at the receptor site. Finally, it is observed that the [4-phenylalanine] analog gave CD curves similar to that of angiotensinamide II. As already mentioned the side chain of tyrosine appeared to be free of interactions and no changes were expected after phenylalanine replacement.

NMR Studies

The data afforded by CD spectra have been supplemented by others originating from NMR measurements. Proton NMR spectra of angiotensinamide II and a variety of its constituant peptides were performed in trifluoroacetic acid[27,28] to assign the signals corresponding to the α carbon hydrogens. On this basis studies were made on angiotensinamide II dissolved in DMSO and in trifluoroethanol. The most clear cut observation is related to the histidine α carbon hydrogen in trifluoroethanol. The integration of the α carbon proton peaks in the region of 4 ppm indicates the presence of 7 protons only, and not 8 as expected, Figure 5. Heating the solution leads to a shift of the water peak towards high field allowing the observation of the last C_α hydrogen previously buried under it, Figure 6. This C_α hydrogen has been assigned to histidine. The frequency (5 ppm) of this histidine C_α hydrogen is more downfield than found in control experiments or in other reports.[29] We suggest that the histidine α carbon experiences a special environment

Figure 5

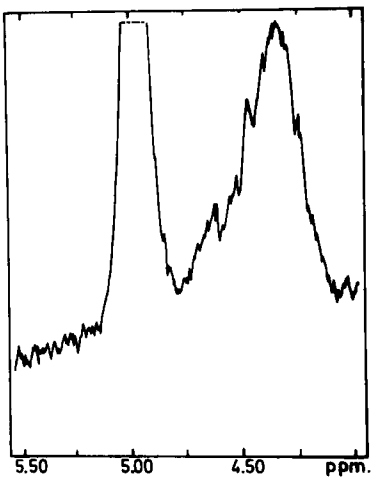

Figure 6

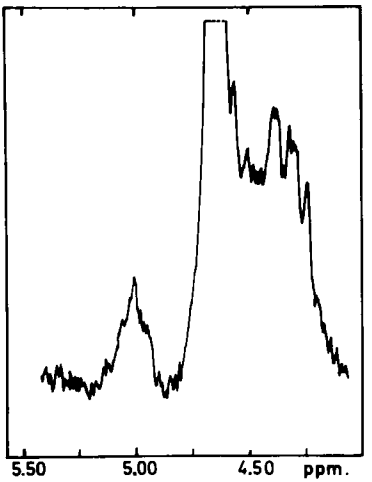

Figure 5: NMR spectrum of angiotensinamide II C_α proton region. Solvent: deuterated trifluoroethanol, concentration 3.10^{-2} *M*, 100 MHz, temperature 23°C.

Figure 6: NMR spectrum of angiotensinamide II C_α proton region. Same conditions as in Figure 5 but at a temperature of 60°C.

due either to the geometry of the proline residue or to specific vicinal interaction, for instance with a carboxylic group.

When angiotensinamide II is dissolved in DMSO, and the solution heated to 60°C, the C_α hydrogen peak moves downfield. This shift compares well with enhanced folding observed by CD in aqueous solution following an increase in temperature. The hydrogens carried by the C_2 and C_4 of the imidazole ring exhibit no shift or broadening in DMSO or in trifluoroethanol at room temperature. The variations of the corresponding peaks in aqueous angiotensinamide II solutions, as a function of pH indicate normal titration curves. Thus, under the conditions investigated, the imidazole ring appears to be free of interactions. This suggests that the imidazole moiety is not involved in

hydrogen bonding or located in hydrophobic regions. This conclusion is entirely supported by the ^{13}C NMR measurements made on the C_2 and C_4 atoms of the histidine side chain,[30] Figure 7. The tyrosine ring gives rise to peaks corresponding

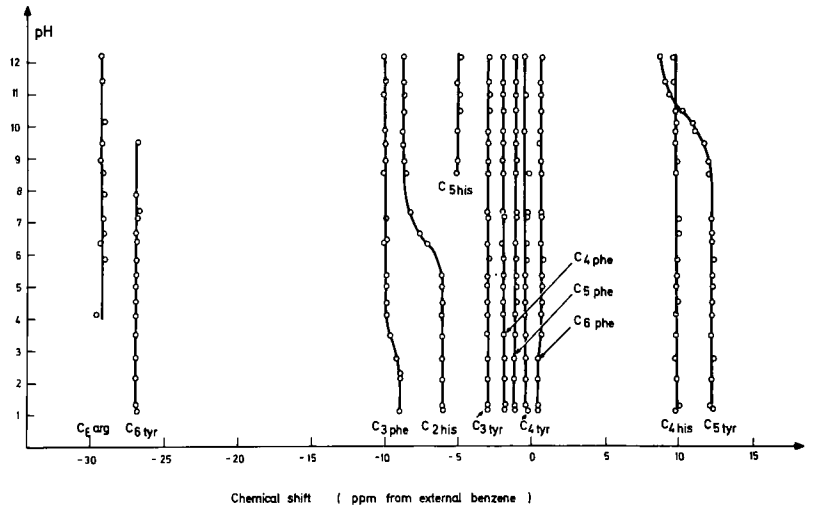

Figure 7: ^{13}C-NMR Titration curves of angiotensinamide II. Solvent D_2O, concentration 6.10^{-2} *M*, 22.6 MHz, temperature 27°C.[30]

to the *ortho* and *meta* aromatic hydrogens. The behavior of the tyrosine residue has been examined in DMSO, trifluoroethanol and trifluoroacetic acid, by H-NMR and in D_2O solutions by ^{13}C-NMR. In all cases tyrosine was found to behave normally, a conclusion, already reached by other methods.[14] This result suggests that the tyrosine side chain seems to be free of interaction, and not surrounded by a hydrophobic area.

Phenylalanine aromatic side chain protons give rise to a single peak. The frequency and the line width of this peak appear normal in DMSO. However it is slightly broadened in trifluoroethanol. The peak assigned to the valine methyl group is also slightly broadened. These changes are not dramatic but may be considered as resulting from mutual interactions.

In this context it might be mentioned here that ^{13}C-NMR of angiotensinamide in DMSO indicates a sharpening of the proline δ carbon as the temperature increases. This gives evidence for a temperature dependent event taking place at proline. A stabilization of the proline residue in a *cis* conformation would fit with these observations, as well as with the shift noted for histidine C_α hydrogen.

NMR examination of the peptide -NH- was first carried out with the tetrapeptide Val-His-Pro-Phe dissolved in DMSO, Figure 8. Through double resonance experiments assignments of the NH and C_α protons were obtained as well as the corresponding coupling constants. It should be noted that the peaks belonging to histidine and phenylalanine NH are broadened and split, respectively. The phenomenona are observed also at the corresponding C_α proton peaks. The frequencies of the peaks in the NH region were plotted as a function of temperature in Figure 9. The NH group assigned to phenylalanine does not shift in the temperature interval studied. This behavior suggests the involvement of the phenylalanine NH group in an interaction, probably a hydrogen bond. In addition the profiles of the peaks corresponding to the C_α protons are not significantly altered. Thus the His-Pro-Phe end of the peptide appears to be stabilized.

Similar experiments were performed with angiotensinamide II, Figure 10. Here again one NH peak does not shift and another moves with a smaller frequency slope, when the temperature is increased. Unfortunately, precise assignment of peaks to individual NH has not been achieved yet because of the overlapping C_α proton peaks. The results indicate however that certainly one and most likely two hydrogen bonds involving -NH- are present in angiotensinamide II dissolved in DMSO. Similar results have been obtained by Jorgensen.[31]

Interpretation of these findings met with the following basic difficulty. In $>10^{-2}$ *M* DMSO solution angiotensinamide II is not present as a monomer but as an aggregate of at least 10 molecules as shown by Rayleigh diffusion techniques.[15] Thus the positive structural evidence obtained by NMR may correspond either to intra- or to interchain bondings. Moreover, the conformation adopted by angiotensinamide II within the aggregates may well be distinct from that in the monomeric state. In this respect, IR and Raman spectroscopy and NMR measurements of aqueous and DMSO solutions are similarly limited. Only in trifluoroethanol do the NMR data correspond to single molecules.

Figure 10: Plot of -NH- proton chemical shifts of angiotensinamide II as a function of temperature. Data obtained at 250 MHz.

An Angiotensinamide II Model

Fortunately among the various techniques used there is an overlap of conclusions: the antiparallel β conformation of solid angiotensinamide II, indicated by IR spectroscopy, supports the interpretation of the CD curves obtained with dry films of the hormone and, due to their similarities, the interpretation of the CD curves of dilute solutions in organic solvents, where angiotensinamide II is monomeric.

The previously stated conclusion[32] that the principal conformation of angiotensinamide II in organic solvents is a cross β type appears thus to be based on solid grounds. The combined data suggest the presence of a turn at the level of valine in position 3 and tyrosine in position 4, and a folding of the end of the molecule due to the rotation of the histidine-proline peptide bond toward a *cis* conformation. This second turn gives rise to a hydrophobic pocket made of valine and phenylalanine side chains on one

side of the molecule and is supported by the CD data, as well as by the NMR findings in trifluoroethanol solution pertaining to the C_α proton of histidine, to the phenylalanine and valine side chains. Changes at the C_α proton of histidine and of the δ carbon of proline observed by NMR when heating DMSO and concentrated aqueous solutions compare well with the heat dependent enhancement of bands seen by CD on dilute aqueous solution, and may represent the same phenomenon: a rotation of the histidine-proline bond towards a *cis* conformation. On the basis of these considerations a model of angiotensinamide II has been built[32] in which the arginine, tyrosine and histidine side chains were left free of interaction. Interestingly enough, the proposed location of the phenylalanine end is not compatible with a replacement of L-histidine by D - histidine without extensive change of the conformation, in agreement with experimental observations (Figure 4). The stabilization of the conformation is attained by hydrophobic interactions and by hydrogen bonding between peptide groups. As a matter of fact, the data of the tritium exchange technique[18] as well as NMR in DMSO solutions both indicate one strong and one weaker hydrogen bond, but under quite different conditions. The hydrogen bonds observed by Printz *et al.*[18] are certainly of intramolecular nature whereas those present in DMSO solution are of uncertain nature for the reason mentioned, even if they were assigned (probably one belongs to phenylalanine NH).

The proposed angiotensinamide II model deserves the following comments. First of all, the forces to which the peptide chain is subjected are a function of the surrounding environment conditions, solvent, pH and temperature. Under given circumstances, their combined effects lead to a higher probability for a certain type of folding. However, local arrangements may well be of nearly equal potential energy, and thus remain undefined in a range of restricted possibilities. For instance, we think that the peptide chain of angiotensinamide II assumes a turn in organic solvents starting with valine in position 3. There are several ways to undergo this turn when considering the peptide linkages.[33,34] It is not at all certain that one of the possibilities is favored to the extent that the others are excluded. We prefer the idea that in solution a variety of local transitions are going on, while the overall features are statistically preserved. This results in a molecular flexibility whose extent depends on the environment. It is by reducing this flexibility that angiotensinamide II could be crystallized.[35]

A second comment concerns the biological significance of the proposed overall conformation. Certainly, the latter originates from data collected under non-physiological circumstances. It is gratifying, however, to note that the proposed model not only fits with data obtained from amino acid substitutions and associated biological response[36] but allows further predictions of what may have happened in terms of conformational changes or triggering of the response. Future work should define more precisely the correlation between specific binding with or without biological response and refinement of the model. Presently the greater rigidity introduced in the [3-proline] analog together with the persistence of a fair amount of biological activity[37] seems to indicate that the model may not be too far from the actual conformation prevailing at the receptor sites.

CHEMISTRY AND BIOLOGY OF PEPTIDES

PROTON MAGNETIC RESONANCE STUDY OF ANGIOTENSIN II (Asn^1, Val^5) IN AQUEOUS SOLUTION

J. D. Glickson, W. D. Cunningham.* Division of Molecular Biophysics, Laboratory of Molecular Biology, University of Alabama School of Medicine, Birmingham, Alabama 35233

G. R. Marshall. Department of Physiology and Biophysics, Washington University School of Medicine, Saint Louis, Missouri 63110

IN ORDER TO CLARIFY SOME OF the controversy over the conformation of angiotensinamide (AII') (Asn^1-Arg^2-Val^3-Tyr^4-Val^5-His^6-Pro^7-Phe^8) in aqueous solution, we have analyzed in some detail the 220 MHz proton magnetic resonance (pmr) spectrum of this hormone in both D_2O and H_2O. Spectra of AII' in D_2O (Figure 1) were measured near the solvent freezing point in order to observe the αCH absorptions, which overlapped at higher temperature with the relatively intense solvent absorption (*H*DO). We assigned resonances to specific hydrogens on the basis of chemical shift estimates for random-coil polypeptides,[1] homonuclear proton spin decoupling experiments, peak intensities, preparation of partially deuterated analogs of AII', and the characteristic pD_c dependence of the chemical shifts of specific resonances (Figure 2b). The following hydrogens had resonances with chemical shifts that differed significantly from values reported by McDonald and Phillips[1] for random-coil polypeptides (which appear in parenthesis): Pro δCH_2 777, 782 Hz (2 x 736 Hz), and Val βCH 2 x 425 ± 10 Hz (2 x 494 Hz). This suggests that except for the Pro and the two Val residues, the sidechains of AII' experienced an essentially solvated environment. The appearance of only

*Present Address: Cancer Research and Training Center, University of Alabama School of Medicine, Birmingham, Alabama 35233.

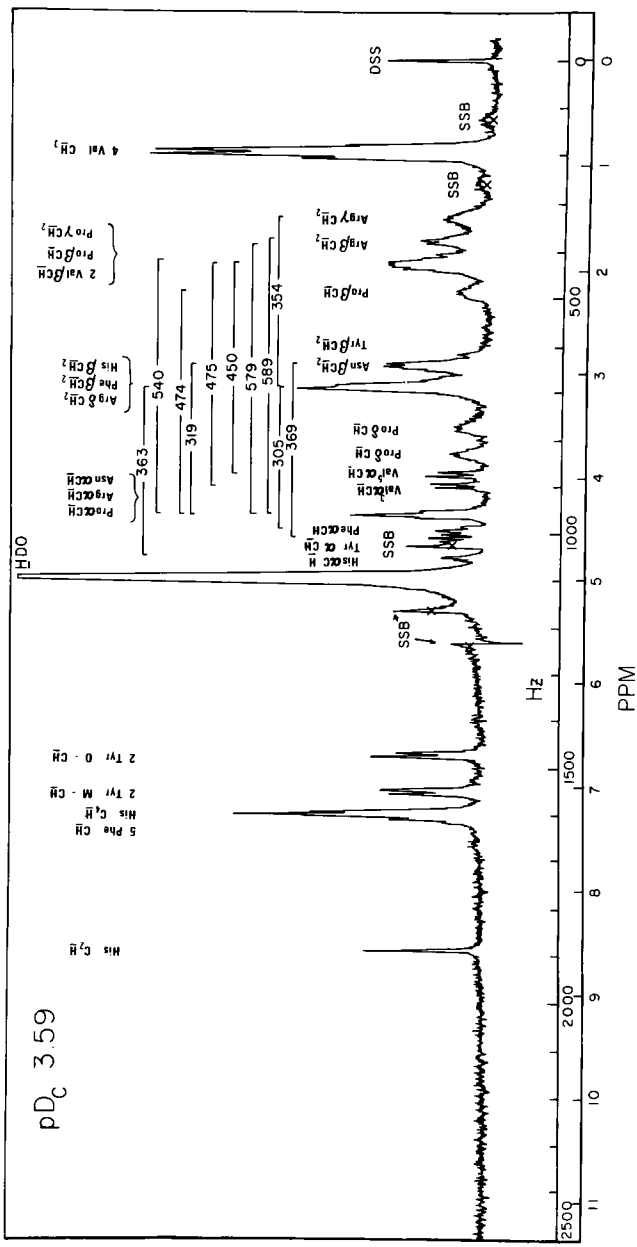

Figure 1: The 220 MHz pmr spectrum of angiotensin II (Asn^1 Val^5) 6% (w/v) in D_2O at 5 ± 2° C and pD_c 3.59 (pH meter reading + 0.40). Chemical shifts are referred to the methyl absorption of 2,2-dimethylsilapentane-5-sulfonate (DSS), the internal standard.

one resonance of unit intensity for every proton of AII' indicates that either the hormone assumes a rigid conformation in aqueous solution, or else transitions between the various orientations of this hormone occur at a rate that is "rapid on the nmr rate scale."

Further evidence consistent with a predominantly solvated conformation was the observation that all the N*H* hydrogens of AII' were completely replaced by deuterium by the time the first spectrum was recorded (*i.e.* 6 min). However, it must be noted that the acidic and basic sidechains of the hormone may exert a pronounced catalytic effect on the deuterium exchange rates,[2] which could make some of the labile hydrogens of AII' appear much more accessible to the solvent than they really are. In spectra of AII' in H_2O solution, we observed six peptide N*H* doublets (labeled #1–#6 in Figure 2a), two distinct Asn primary amide N*H* peaks, and a broad three proton Arg-NH-C(NH)-N*H*$_3$ resonance in the 1400-2000 Hz region of the spectrum, which also contained the aromatic C*H* absorptions (Figure 2a). Broadening of N*H* resonances as the pH was raised results from basic catalysis of the exchange of hydrogens between the NH groups and water. If allowance is made for the different chemical shifts of the various N*H* absorptions, a rough measure of the relative exchange rate of a given N*H* hydrogen is the pH at which its resonance broadens out--the lower this pH, the more rapid the exchange. On this basis peptide N*H* #1 and the Arg guanidino protons exchange most rapidly, peptide proton (#4 = Phe) exchanges least rapidly and the remaining peptide and carboxamide protons exchange at intermediate rates. The C-terminal Phe N*H* resonance is distinguished by the pH dependence of its chemical shift (pK_a 3.07) (Figure 2a). The C-terminal Gly residue of Gly-Ala-Gly behaved similarly (pK_a 3.15). Since a negatively charged C-terminal group is expected to destabilize the amide anion transition state for proton exchange,[3] whereas a positively charged N-terminal group is expected to stabilize this species, anomolously slow and fast exchange rates are expected on purely inductive grounds for the Phe and the Arg peptide N*H* hydrogens, respectively. This leads us to suspect that peptide NH #1 may be Arg.

The peptide N*H*-α*CH* coupling constants: 6.5 ± 0.3, 6.0 ± 0.5, 7.2 ± 0.5, 7.3 ± 0.3 (Phe), 7.9 ± 0.3, and 8.0 ± 0.4 Hz for peptide resonances #1–#6, respectively, exclude a right handed α-helix (about 2 Hz), and indicate that AII' assumes a different conformation in H_2O than the conformation assumed in dimethylsulfoxide by a related heptapeptide investigated by Weinkam and Jorgensen.[4] This

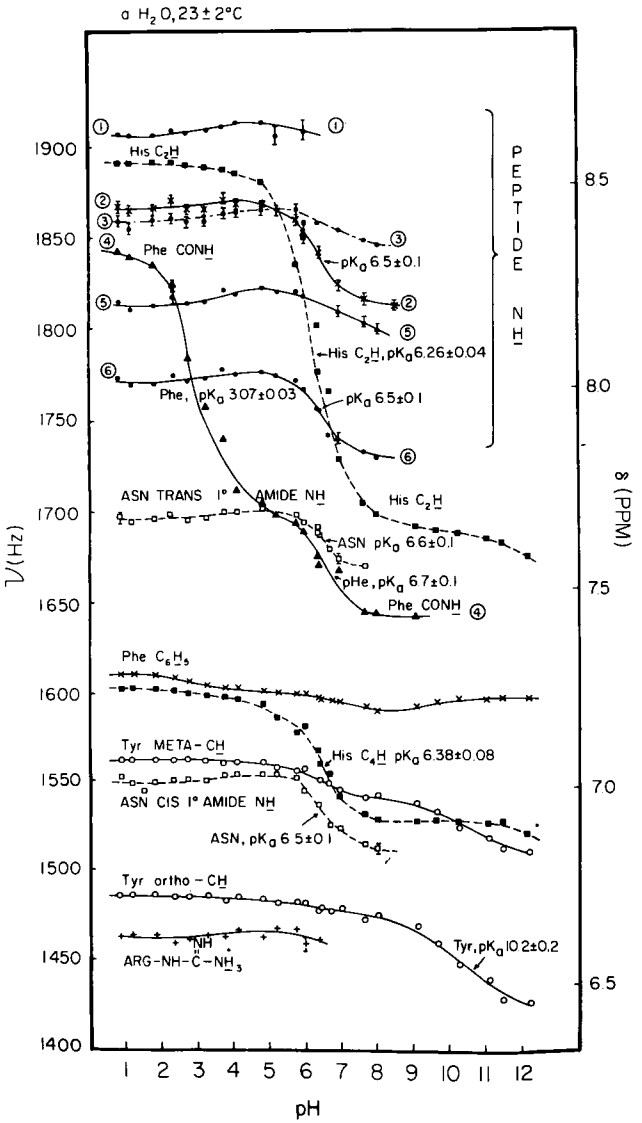

Figure 2: Chemical shifts at 220 MHz of angiotensin II (Asn^1 Val^5 (a) resonances to low field of the solvent absorption in H_2O solution at 23 ± 2° C as a function of pH, and (b) of resonances to high field of the *H*DO

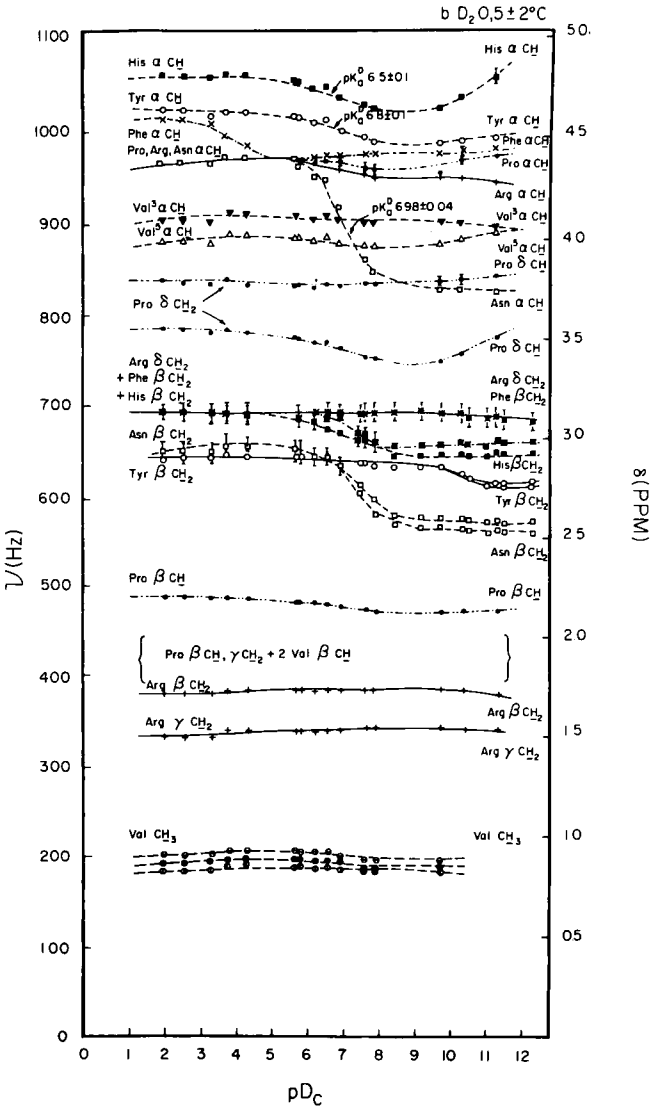

resonance in D_2O at 5 ± 2° C as a function of pD_c. The acidity of the solutions was adjusted with HCl and NaOH in H_2O and their deuterated analogs in D_2O. The sodium error was significant above pH (pD_c) 10.0 and has not been corrected for.

heptapeptide had two peptide hydrogens with coupling constants less than 3 Hz. The coupling constants of AII' are, however, consistent with a random-coil (6.1 Hz)[5] β-structure (7-8.5 Hz), or perhaps some other orientation.

The pK_a's associated with the titrations in Figure 2 were: carboxyl 3.07 ± 0.03 (3.0 ± 0.1), imidazole 6.26 ± 0.04 (6.82 ± 0.02), α-amino (6.98 ± 0.04), and phenol 10.2 ± 0.2 (10.5 ± 0.2), where the figures in parenthesis were obtained in D_2O and reflect the hydrogen-deuterium isotope effect. Comparison with data from small peptides[6] indicates that the α-amino group is anomolously acidic.

The simultaneous perturbation of all the amide resonances (Figure 2a) suggests a conformational change with a pK_a of 6.6 ± 0.2, indicative of involvement of both imidazole and α-amino groups. Addition of guanidine significantly affected the spectrum of AII' on the acid side of this transition, but not on the basic side. These results are consistent with the thin-film dialysis data of Craig *et al.*[7] which showed a transition of AII' from a coiled conformation in acid to a more extended conformation in base. The reported greater activity of AII' in basic solution might result from exposure of critical functional groups of AII' in basic, but not acidic, solution. The nature of the acid stable conformation is not yet clear.

Acknowledgments

The authors are indebted to Dr. Dan W. Urry for financial support, the use of laboratory equipment, and helpful discussion of the data. The assistance of William Vine in analysis of the data is gratefully acknowledged. This research was supported by grants from the Mental Health Board of Alabama (to D.W. Urry), the Public Health Service Grants AM 13025 and HE 14509, and the American Heart Association (Established Investigator Grant to G. R. Marshall).

CHEMISTRY AND BIOLOGY OF PEPTIDES

CONSTRAINTS ON THE RECEPTOR-BOUND CONFORMATION OF ANGIOTENSIN II

Garland R. Marshall, Heinz E. Bosshard, Nancy C. Eilers, Philip Needleman. Departments of Physiology and Biophysics and of Pharmacology, Washington University School of Medicine, St. Louis, Missouri 63110

ONE APPROACH TO THE PROBLEM of the biologically active conformation[1] is to reduce the inherent conformational flexibility available to the structure. We have systematically investigated from a theoretical viewpoint the restrictions on conformational freedom of the peptide backbone introduced by increasing the steric bulk of groups which are located on the peptide backbone. In particular, we have investigated the replacement of the hydrogen atoms of the peptide backbone, Figure 1, by methyl groups[2,3] which gives an increase in the Van der Waals' radii from 1.2 angstrom to 1.85 angstrom. There are three categories of proton replacements to be examined (Figure 1): 1) Replacement of the amide proton of the amino acid under investigation with a methyl group to give an *N*-methyl amino acid; 2) Replacement of the alpha proton to give an alpha methyl amino acid; 3) Replacement of the amide proton of the subsequent amino acid residue by a methyl group, *i.e.* the effect of an *N*-methyl amino acid on the preceding residue. Two simplifying assumptions are 1) the peptide group is planar due to partial double bond character of the amide bond, and 2) the methyl group can be treated as a sphere, due to rapid rotation, rather than discrete atoms. The position of all the atoms in space up to the beta carbon of the side chain are then determined by the torsional rotations about the bond between the amide nitrogen and alpha carbon (ϕ) and the bond between the alpha carbon and the carbonyl carbon (ψ).

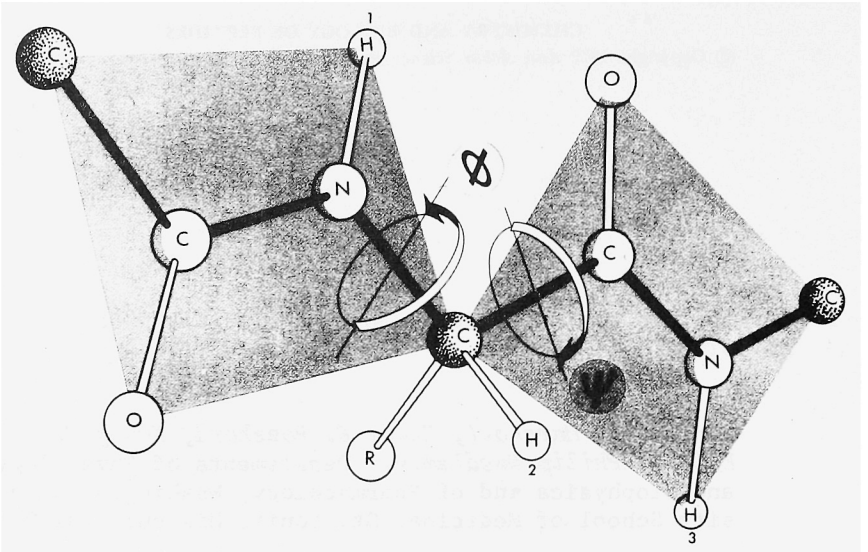

Figure 1: Two linked peptide groups whose conformation is determined by the dihedral angles ϕ and ψ which refers to torsional rotations about the single bonds passing through the alpha carbon. Replacement of hydrogen number 1 gives an *N*-methyl amino acid; hydrogen number 2 gives an α-methyl amino acid; and hydrogen number 3 gives an amino acid preceding an *N*-methyl residue. (Adapted from Dickerson and Geis. *The Structure and Action of Proteins*, Harper & Row, 1969).

In the calculations programs developed for a small laboratory computer (LINC, μLINC, or PDP-12) were used which consist of a set of general input and manipulation programs, CHEMAST,[4] and a program for iterative searches of conformationally dependent variables, BURLESK.[5] Such programs were necessary because the long calculation times made use of a computational center both too demanding and too expensive. The CHEMAST program allows the input of a chemical formula through a linear string of chemical groups; *i.e.* CH3, CO, NH, *etc.* The program then calculates the appropriate atomic co-ordinates and connectivity for the molecule based on a dictionary which specifies the geometry and bond distances of the appropriate chemical groups. A stick figure representation of the model can be displayed and manipulated on the display scope or the molecular description handed over to more complex programs such as

BURLESK for iterating exhaustively the possible conformations and calculating variables such as potential energy. Initial calculations[6,7] were based on the assumption of a hard sphere for the atoms. One difficulty in interpretating results of hard sphere calculations is that there is no indication of the probability of a given conformation. Agreement between conformations obtained from crystallographic studies of protein molecules and those predicted by these calculations, while relatively good, has some striking discrepancies.

The Kitaigorodsky potential function[8] gives an excellent fit between the values calculated for *N*-acetyl-L-alanine methyl-amide and the dihedral angle values determined for lysozyme.[9] We have extended the comparison (Figure 2) to six proteins: myoglobin,[10] lamprey hemoglobin,[11] insulin,[12] carboxypeptidase A,[13] and cytochrome B_5.[14] Over 89% of the 847 non-glycine values examined are within 1 kcal/mol of the calculated potential minima and over 95% are within a 2 kcal/mol contour.[15]

The contours for acetyl-*N*-methyl-L-alanine methylamide are shown in Figure 3. Further justification of the choice of the Kitaigorodsky function and the contouring level is given by crystallographic values for the only *N*-methyl amino acid found in proteins, proline. Since the torsional rotation about the amide-alpha carbon bond (ϕ) in proline is required to be approximately -60° by the cyclic imide, all data must center around this value and are, thus, found between the one and two kcal/mol contour for *N*-methyl alanine. The contours for an amino acid preceding an *N*-methyl amino acid are compared with the crystallographic values for amino acids preceding proline in Figure 4. Note that the allowed area is limited to positive ψ values except for a small region between one and two kcal/mol around the right-handed alpha helix region (ϕ = -57°, ψ = -47°). The contours obtained for acetylaminoisobutyric acid methylamide (alpha methyl alanine) is shown in Figure 5. Particularly striking is the marked restriction in flexibility already indicated in the hard sphere calculations and the preference for those torsional values associated with either a right- or a left-handed helix (ϕ = -57°, ψ = -47°; ϕ = 57°, ψ = 47°).

We are primarily interested in the interaction of a small peptide, angiotensin II, with its macromolecular receptor. Potential energy calculations would have to involve the receptor as well as angiotensin to indicate a particular receptor-bound conformation. Calculations on the peptide alone might be useful, however, in indicating

Figure 2-4 show Kitaigorodsky potential energy plots contoured at X kcal/mol above the potential minimum (determined with K_2 parameters).[7]

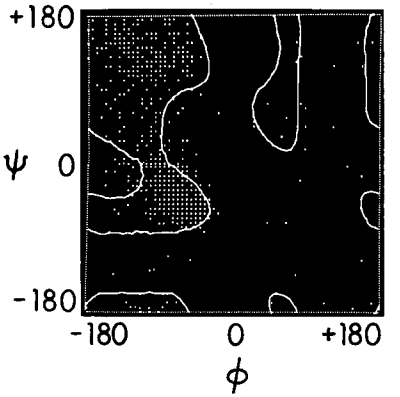

Figure 2: *N*-Acetyl-L-alanine methylamide, X = 1. Points are dihedral values determined for myoglobin, insulin, lamprey hemoglobin, carboxypeptidase A, cytochrome B_5, and ribonuclease S.

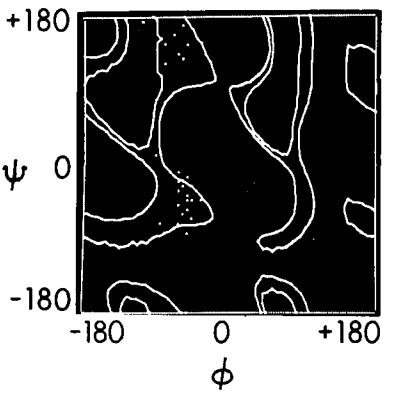

Figure 3: Acetyl-*N*-methyl-L-alanine methylamide, X = 1 and 2. Points refer to dihedral values determined for proline for six proteins.

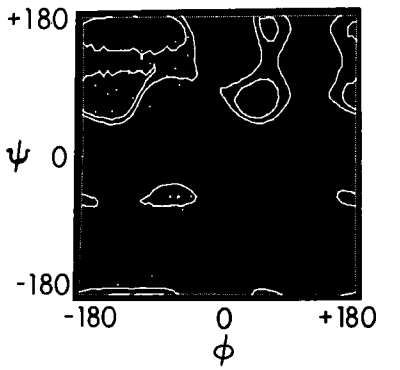

Figure 4: *N*-Acetyl-L-alanine dimethylamide, X = 1 and 2. Points refer to amino acids which precede proline for six proteins.

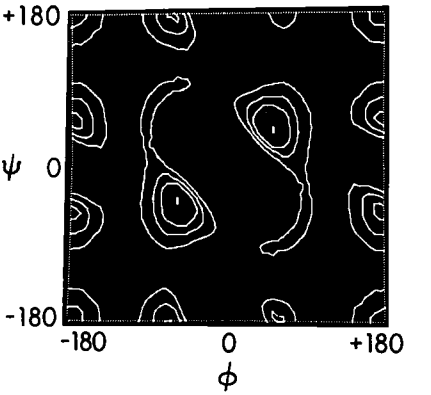

Figure 5: *N*-Acetylaminoisobutyric acid methylamide, X = 0, 0.5, 1 and 2.

those peptide conformations which were so energetically unfavorable that interaction with the receptor would be unlikely to induce their presence. In other words, given an estimate of the energy difference which might be overcome as a result of intermolecular interaction, one would be able to interpret the potential energy diagrams in terms of allowed vs. disallowed areas. A sampling of possible intermolecular interaction energies and their likelihood of introducing deviations from the local potential minima is found in a protein molecule. The excellent agreement between the values of the torsional rotations (ϕ, ψ) actually found in proteins and those calculated as being less than 2 kcal different from the potential minima for a single amino acid derivative is striking. It implies that deviation from a local potential minimum is not common in proteins and, therefore, not likely in the interaction of a peptide hormone with its receptor.

A variety of angiotensin analogs containing *N*-methyl and alpha methyl amino acids have been synthesized and their biological activities studied. Interpretation of their biological activity in terms of conformational restraints imposed by these unusual amino acids leads to certain conclusions regarding the receptor-bound conformation.[16] The case for residue 5 is illustrative. A proline substitution at this position retains 10% activity.[17] This requires a ϕ value of approximately -60° at position 5 due to the cyclic nature of the proline ring. Cycloleucine (1-aminocyclopentanecarboxylic acid) when substituted at position 5 maintains 24% activity.[17] This amino acid has the same steric restraints as aminoisobutyric acid, and requires ϕ_5 and ψ_5 to be either -57°, -47° or +57°, +47°, respectively. The simplest conclusion is that the active conformation at position 5 is that common to both proline and cycloleucine, *i.e.* $\phi_5 = -57°$, $\psi_5 = -47°$, or the right-handed alpha helical values. The proline substitution at position five also affects the conformational freedom at position four, making a positive value for ψ_4 likely.

The proline at position 7 of the hormone requires ϕ_7 to be approximately -60°. The requirement for the *N*-methyl amino acid at that position is seen by the fact that the *N*-methyl alanine substitution[18] retains 22% pressor activity while an alanine substitution[19] has less than 1% activity. This implies a role for the *N*-methyl residue in positioning the preceding residue, making a positive value for ψ_6 likely.

Position 3 normally contains valine, but a proline substitution retains 40-80% of the activity.[20] The torsional rotation ϕ_3 has, therefore, a receptor-bound value near -60°.

Substitution of either aminoisobutyric acid[6] or cycloleucine[21] retains only 1% activity. Since this activity is approximately that obtained for the C-terminal hexapeptide alone[22] and residue 3 positions residues 1 and 2, this level of activity is not considered significant. It is tempting, therefore, to conclude that of the two probable conformations available to proline at position 3, $\psi_3 \simeq -47°$, or $\psi_3 \simeq 120°$, the most likely one at the receptor is that where $\psi_3 \simeq 120°$ since $\phi_3 = -57°$, $\psi_3 = -47°$ which is possible for either aminoisobutyric acid or cycloleucine is not effective. The activity of the proline substitution probably makes the value of ψ_2 positive.

Resolution of alpha methyl analogs of amino acids by deacylation with carboxypeptidase A[23] has made appropriate derivatives available such as alpha methyl-L-phenylalanine which is currently being incorporated into angiotensin analogs. This should provide additional information on positions 4 and 8.

Either the receptor conformational specificity for angiotensin is not as great as one has suspected from previous studies in that several different backbone conformations can give high levels of biological activity or the constraints derived from the analog studies apply to the receptor-bound conformation. It is of considerable interest to compare these constraints with those obtained by solution studies. In particular, the values for the receptor-bound conformation of angiotensin II for the torsional rotations $\phi 3$ and $\phi 5$ are of interest. Because of the activity of the two proline analogs at positions 3 and 5 and the ring constraint which limits the ϕ rotation to $-60° \pm 15°$, one can assume the active conformation has a similar rotational angle at the receptor. The value of this angle can be determined by PMR from the coupling constant between the amide hydrogen and the alpha proton. A value of $-60° \pm 15°$ would give a coupling constant of 2 ± 1 Hz.[24] In aqueous solution, all of the amide protons have been observed and have coupling constants of 6 Hz or greater.[25] This implies a conformational transition on binding of angiotensin to its receptor. One might argue that a nonpolar environment might be more comparable to that of the receptor which is assumed to be membrane-bound and whose interaction with angiotensin II may well be hydrophobic in nature. Measurement of the coupling constants for the amide protons associated with Val^3 and Ile^5 in des-Asp^1-[Gly^2]-angiotensin II in dimethylsulfoxide (DMSO) give values of 7.5 and 8.5 Hz respectively.[26] This implies that DMSO does not induce the conformation which is postulated at the receptor.

In conclusion, theoretical analysis of rotational freedom of the backbone has placed certain constraints on possible backbone conformations available to certain analogs of angiotensin II which show high levels of biological activity. One must, therefore, assume that these constraints are operative during binding to the receptor and subsequent processes leading to the biological action of angiotensin II. It is of particular interest that these constraints are different than those which have been determined for the solution conformation of angiotensin II. One must, therefore, conclude that a conformational transition occurs in the peptide upon binding to the receptor. Consequently, future care must be exercised before one attempts to interpret the biological activity of peptides based on their solution or even crystalline conformations.

SYMPOSIUM DISCUSSIONS

Summarized by Johannes Meienhofer

THE REVIEW ON THE physiological roles of angiotensin (Peach, pp 471 to 493) was followed by an interesting discussion touching on comparisons with norepinephrin and ACTH action, on *in vivo* stability of angiotensin, clinical testing of inhibitors and effects on the nervous system. [1-Asparagine]-angiotensin II seems to be more active than [1-aspartic acid]-angiotensin II on papillary muscle preparations because it is less readily degraded. When the degradative enzymes were flushed out of the tissue beforehand, the dose response curves of the two compounds came close together. The degradative enzymes have never been isolated, but most of *in vivo* angiotensin degradation seems to occur by circulating enzymes.

Interpretations of structure-activity correlations become increasingly specific (pp 495 to 520). A discussant cautioned from interpreting too categorically relationships between affinity and intrinsic activity. With cysteine-containing analogs (*e.g.* [Cys^8]-angiotensin II), it is uncertain whether the sulfhydryl form is maintained throughout an assay. More analogs with potent inhibitory activity have been obtained, and the effects of [Sar^1, Ile^8]- and [Sar^1, Leu^8]-angiotensin II also appear to be extremely long lasting *in vivo* due to their resistance to aminopeptidase degradation. In response to an inquiry whether 1-deamino-angiotensin has been synthesized, it was pointed out that deamino-[Sar^1]-angiotensin II had diminished activity (see also ref. 1, 2).

Applauded was a short but concise description (Jorgensen) of "syntheses of analogs of angiotensin" by the solid-phase technique where preparations undergo the following sequential purification: (i) countercurrent distribution, (ii) Sephadex

chromatography, and (iii) CM-cellulose chromatography. The products are tested by: (a) NMR, (b) tlc in 6 solvent systems, (c) high voltage electrophoresis at two different pH values, (d) amino acid analysis, and (e) hydrolysis and L-amino acid oxidase studies to detect racemization. Complete homogeneity must be observed in all tests.

Synthesis of bio-isosteres of a peptide renin inhibitor (pp 541 to 544) were complemented as the addition of another dimension in analog synthesis. Very likely, the chemistry will be even more complicated than in straight peptide synthesis.

One comment alluded to multiple mechanisms of action in potentiating effects on bradykinin through inhibition of bradykininases.

A most enjoyable discussion developed about angiotensin conformation following Dr. Fromageot's lecture (pp 545 to 562). Determination of the molar ellipticity and the importance of concentration in the measurements of conformation in solution became objects of discussion. It was also pointed out that peptides might undergo changes in certain organic solvents, as DMSO, dichloroethanol, trifluoroethanol, etc. to the extent that the material could sometimes not be recovered. Therefore, peptides should, after studies in organic solutions, always be recovered, and their integrity be checked. Trifluoroethanol was carefully redistilled before CD measurements of angiotensin were done; finally it crystallized from this solvent with fully intact biological potency. The question whether two forms of angiotensin, separable by Sephadex chromatography or by thin film dialysis represent two stable conformations or two states of dispersity remained unsettled. Apparently, CD spectra of the two forms appear to be indistinguishable. An argument about which form of the His-Pro bond is to be called *cis* and which *trans* illustrated the importance of defining, perhaps for each individual study, the terminology used (compare footnote, p 545). Discussions on similarities of established peptide conformations to those at receptor sites remain as pure conjecture, as those on the sex of an unborn baby, but they continue to come up with the same regularity. Similarly, the nature of the binding forces remains anyone's guess, but topochemical studies might provide information on spatial requirements. Thus, modification of the arginine residue in position 2 by reaction with cyclohexane dione to give an imidazolidine derivative does not impair the activity, indicating that the guanidine group is not located near an aromatic residue or a narrow

cleft of the receptor. In dilute aqueous solution angiotensin is so flexible that one cannot define a conformation, although it is far from random, and a certain degree of folding is apparent from results of tritium exchange.

CHEMISTRY AND BIOLOGY OF PEPTIDES

THE HYPOTHALAMIC HORMONES--THEIR SIGNIFICANCE IN PHYSIOLOGY AND MEDICINE

Roger Guillemin. The Salk Institute, La Jolla, California 92037.

SUMMARY--A short review describing the concept of central nervous system control of endocrine function through hypothalamic pituitary afferents, the hypothalamic hypophysiotropic hormones. It discusses further the significance of the recent characterization and total synthesis of two of the hypothalamic hypophysiotropic hormones in terms of current endocrinology. The use of the hypothalamic hypophysiotropic hormones in many aspects of clinical endocrinology is discussed including the possibility of the use of synthetic analogues as a novel approach to contraceptive medication.

SINCE THE END OF THE LAST CENTURY, it has been realized that the two major systems maintaining the homeostasis of the organism were the central nervous system and the endocrine glands. The anterior lobe of the pituitary gland or adenohypophysis was also shown to be the major controller of the secretion of other (peripheral) endocrine tissues, while the posterior lobe of the pituitary gland or neurohypophysis was shown to secrete oxytocin and vasopressin.

Until recently, it was considered that the major, if not sole, mechanism of the regulation of secretion of adenohypophysial hormones was to be found in an ensemble of simple *negative feedback* systems whereby the plasma concentrations of peripheral hormones from the gonads, the adrenal cortex, the thyroid, were in inverse relationship to the amount of the corresponding pituitary hormones

secreted. The explanation for these negative feedback systems was simply in terms of a direct action of the peripheral hormones on the pituitary gland to regulate somehow its secretion. We will see later that if the feedback systems are still considered an important part of the mechanism of control of the pituitary secretions, we now have proof that they work through the central nervous system in the case of the gonadal and adrenal steroids or in conjunction with it, in the case of the thyroid hormones.

A possible directing role of the central nervous system in the control of the secretion of adenohypophysial hormones was first suspected from numerous observations showing that many exteroceptive stimuli triggered the secretion of pituitary hormones; exposure to cold environment stimulates secretion of TSH, nocuous stressing agents stimulate secretion of ACTH and growth hormone, and experimentally varying amounts of light or light-darkness ratios will in many species, from birds to mammals modify secretions of the gonadotropins, hence sexual receptivity and reproduction patterns.[1]

Following these early observations, it is now well established that the central nervous system participates in the physiologic mechanisms which regulate the secretions of the anterior lobe of the pituitary gland. For instance, minute electrocoagulations of discrete areas of the (ventral) hypothalamus (Figures 1, 2 and 3) specifically interfere with secretion of ACTH,[2] TSH,[3] the gonadotropins-luteinizing hormone (LH),[4] follicle-stimulating hormone (FSH),[5] and growth hormone (somatotropin, STH).[6] Conversely, localized stimulation with electrical currents in specific hypothalamic loci will stimulate secretion of ACTH,[2] TSH,[3] gonadotropins[4,5] and growth hormone.[6] Furthermore, secretion of pituitary hormones such as ACTH or the gonadotropins has been shown to be accompanied by changes in spontaneous electrical activity of the pertinent hypothalamic areas or nuclei.[7] In all cases mentioned so far, it appears that the hypothalamus contributes *stimulatory* inputs for acutely increasing the secretion of a pituitary hormone over some sort of a basal secretion which appears to take place in absence of hypothalamic stimulus.

Secretion of two other pituitary hormones, prolactin and MSH (or melanocyte stimulating hormone) may be, on the other hand, under some sort of a tonic *inhibition* by the hypothalamus: Indeed, separation of the adenohypophysis from its normal hypothalamic connections leads to increased secretion of prolactin[8] and MSH.[9]

The negative feedback mechanism which we mentioned earlier, in which a peripheral hormone inhibits secretion

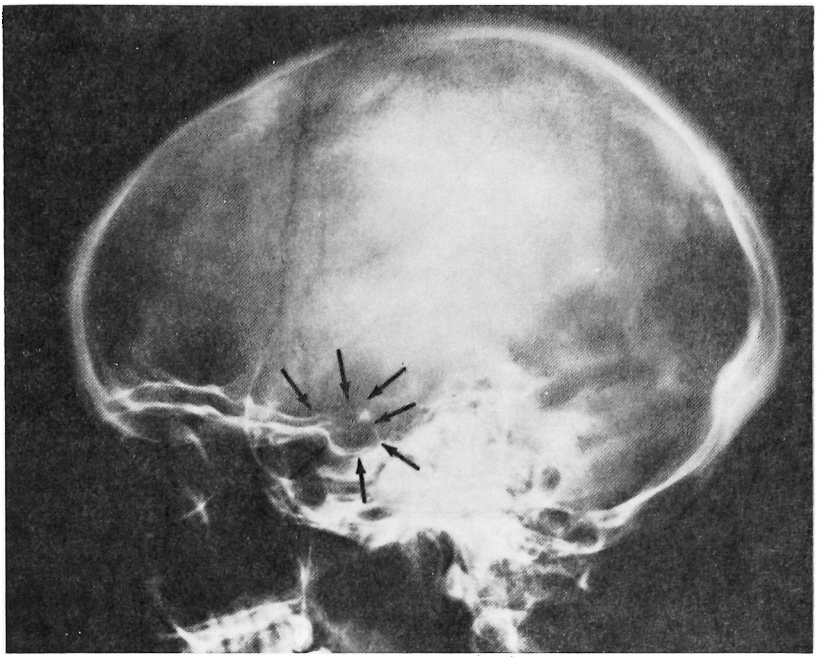

Figure 1: X-ray of the skull of a normal adult man. The pituitary gland is ensconsed in a spherical cavity of the sphenoid bone (arrows); the part of the brain immediately subjacent to it is the hypothalamus area (arrows).

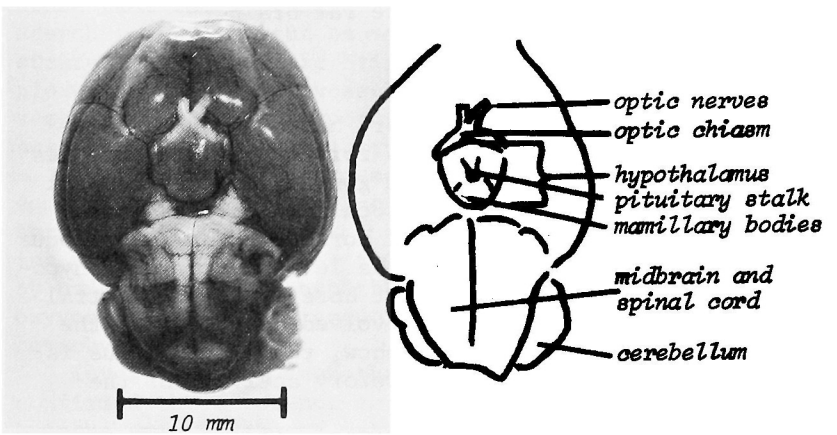

Figure 2: Ventral view of the rat brain.

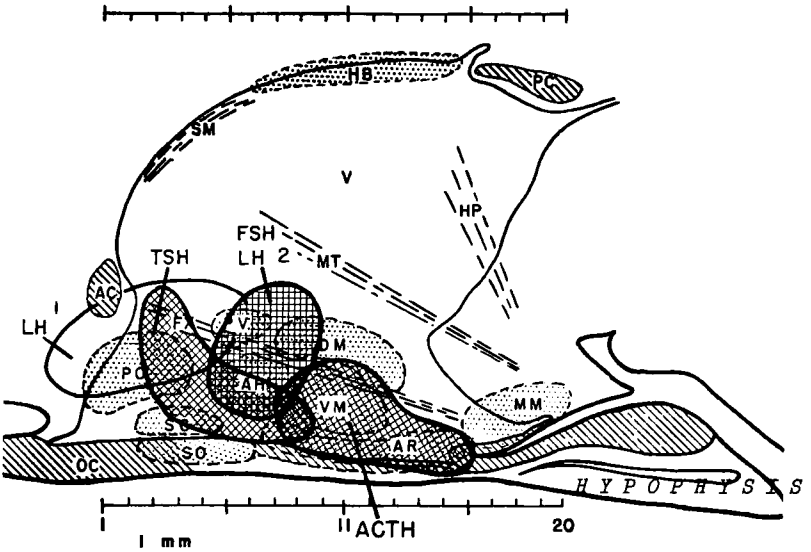

Figure 3: This simplified diagram shows four areas circled in black lines on a sagittal section of the hypothalamus (brain of the rat) which are primarily related, respectively, from left to right with the secretion of LH, TSH, FSH and LH, ACTH. The diagram attempts to show that these areas overlap considerably, one upon another; further, that these "hypophysiotropic" areas do not coincide with the classic nuclei of the hypothalamus described by neuroanatomists--OC, optic chiasm; AC, anterior commissure; PC, posterior commissure. Other abbreviations are given as in the de Groot atlas of the rat brain.

of the pertinent pituitary factor, has been shown to be exerted through the hypothalamus for the steroid hormones of the adrenal cortex and of the gonads, as the feedback mechanisms can be abolished by localized hypothalamic lesions. In the case of thyroid hormones, the major locus of the negative feedback is at the level of the adenohypophysis and we will see later that here again the central nervous system is nonetheless involved also. Thus, the evidence is now clear that, somehow, the hypothalamus is involved in controlling the secretory activity of the adenohypophysis.

The hypothalamus is a phylogenetically ancient part of the brain which receives a large number of connections from

other parts of the encephalon. Neural systems afferent to the hypothalamus (midbrain reticular formation, limbic system) participate also in the transhypothalamic control of the secretion of the adenohypophysis. For instance, localized experimental lesions of the fornix, the septum, the amygdala and the olfactory tract, *i.e.*, fiber tracts or nuclei connected to the hypothalamus, will interfere with the release of the gonadotropin hormones, particularly ovulation hormone (LH).[10,11] Similarly, ovulation is accompanied by characteristic changes in the electrical activity of these centers.[10] It is known also that lesions in the midbrain reticular formation will interfere with secretion of ACTH and TSH.

What is the mechanism whereby the information of hypothalamic origin is conveyed to the adenohypophysis? In contradistinction to the large tract of nerve fibers connecting the hypothalamus and the neural lobe of the pituitary, the source of secretion of the two octapeptides vasopressin and oxytocin, no similar nervous connection exists between hypothalamus and adenohypophysis. There is, however, between these two structures, a well-developed system of capillary vessels (Figure 4): The hypothalamo-hypophysial portal system, with its primary plexus in the junction area between hypothalamus and adenohypophysis (median eminence), and collecting veins around and in the pituitary stalk and its secondary plexus throughout the parenchyma of the anterior lobe of the pituitary; blood flow is definitely from primary to secondary plexus, *i.e.*, from hypothalamus to adenohypophysis. The concept thus arose that the hypothalamic control of secretions of the adenohypophysis might be *neurohumoral* in nature, some substance of hypothalamic origin being released in the primary plexus of the portal vessels to be transmitted by these vessels to the adenohypophysis where it would stimulate secretion of pituitary hormones.

The concept of neurosecretion, *i.e.*, the ability of some highly specialized neurons to secrete substances with hormonal activities was long established from studies dealing with invertebrates;[12] in mammalians, it is supported by evidence for the hypothalamic origin of vasopressin and oxytocin which are transported by axoplasmic flow to the neurohypophysis.[13]

Investigations over the last few years have indeed confirmed the existence in crude aqueous extracts of hypothalamic tissue of substances capable of specifically stimulating the secretion of ACTH, TSH, gonadotropins and growth hormone. Similarly, it appears that some substances

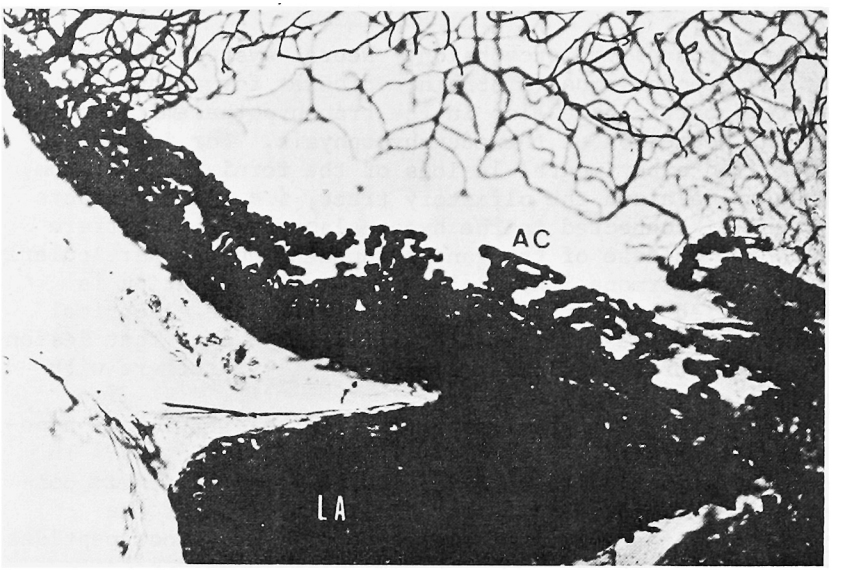

Figure 4: Sagittal section of the ventral hypothalamus (median eminence) and anterior pituitary (rabbit) after intracarotid injection of India ink. Loops of capillary vessels (AC) can be seen in a network that establishes contact with nerve fiber terminals (not shown) of hypothalamic origin; these capillary vessels merge into larger vessels that carry blood to the anterior lobe of the hypophysis (LA). Photograph, courtesy of Professor H. Duvernoy, Department of Anatomy, School of Medicine, Besançon, France.

in the same crude extracts of the hypothalamus inhibit the secretion of prolactin and MSH (and possibly also growth hormone). These substances of hypothalamic origin, modifying the secretion of pituitary hormones, have been termed *hypophysiotropic hormones* or *releasing factors*; in the case of prolactin, MSH and possibly growth hormone, we talk of *hypophysiotropic inhibitory hormones* or *release-inhibiting factors*.[14]

Recent observations have shown that we are dealing with different chemical entities for each one of these hypophysiotropic activities. There is now good evidence that acidic extracts of the hypothalamus of a series of mammalian species contain specific substances, which all appear to be relatively small polypeptides, involved in the control of the secretion of ACTH (CRF, for corticotropin-releasing factor),

of the gonadotropins LH and FSH (LRF, for luteinizing-hormone-releasing factor, FRF, for FSH-releasing factor) and TSH (TRF, for thyrotropin-releasing factor).[14]

Regarding the control of the secretion of growth hormone, prolactin, and the melanocyte stimulating hormone (MSH), there is some experimental evidence for the existence of releasing factors (GRF, growth hormone releasing factor; PRF, prolactin releasing factor; MRF, MSH-releasing factor) as well as factors inhibiting the release of these three hormones (referred to as SRIF, somatotropin or growth hormone-release inhibiting factor; PRIF, prolactin-release inhibiting factor; MRIF, MSH-release inhibiting factor).[14]

What is known about the nature of these hypothalamic hypophysiotropic hormones?

After several years of arduous work, principally in two laboratories, and collection of several millions of fragments of sheep or pig hypothalamic fragments, two of these hypothalamic-hypophysiotropic hormones have recently been characterized. In 1969, thyrotropin releasing factor was isolated and characterized as the tripeptide <Glu-His-Pro-NH_2.[15-17] In 1971, the luteinizing hormone releasing factor, LRF, was characterized as the decapeptide <Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2.[18-21] TRF and LRF have the same respective primary sequences in the two species, ovine and porcine, from which they were isolated. TRF and LRF characterized as above, have been shown to be highly potent in stimulating respectively the secretion of TSH and LH in a variety of mammalians, including the human. Recently it has been reported that the tripeptide TRF is also highly active to stimulate the secretion of prolactin in humans;[22] from results obtained in other species, it is already apparent that there is a considerable variation in this ability of TRF to release prolactin in various species of animals. Also, it has been reported that one may be able to stimulate differentially the secretion of prolactin and TSH in humans. Thus, TRF may be closely related structurally to the still hypothetical prolactin releasing factor, PRF.

Of interest is the now well characterized observation that highly purified native LRF of porcine or ovine origin, as well as synthetic LRF-decapeptide preparations, are able to stimulate the secretion of not only the gonadotropin LH but also the other gonadotropin, FSH.[15-21] (Figure 5) The proposal has thus been made[23] that the decapeptide LRF may be the sole hypothalamic controller for the secretion of the two gonadotropins, LH and FSH. This hypothesis still leaves unanswered a series of physiological observations

Figure 5: Induction of ovulation in rabbits by a single intravenous injection of the synthetic decapeptide LRF. The globular formations seen at the surface of the control ovaries (upper row) are mature follicles typical of the mature virgin rabbit. 24 hours after injection of LRF, (lower row) many of these follicles appear turgescent and very black on the photograph; they have ovulated and their dark appearance in the photograph is due to their being filled with blood following ovulation (corpora haemorrhagica or Blutpunkt).

in which there is evidence for dissociated releases of FSH and LH. Thus, at the writing of this short review, the question of the possible existence of a specific FSH releasing factor (FRF) distinct from the decapeptide LRF, still remains open for further investigations.

The postulated growth hormone releasing factor (GRF) has not been characterized. A decapeptide with the primary sequence Val-His-Leu-Ser-Ala-Glu-Glu-Lys-Glu-Ala has recently been isolated from hypothalamic tissues of porcine origin and proposed by Schally *et al.*[24] as being the hypothalamic controller of growth hormone secretion, "GRH or growth hormone releasing hormone." The significance of this material is, at the moment, very much open to question, since it appears to be active only in one type of bioassay which has not been fully characterized, while it is unable to stimulate the secretion of growth hormone in a variety of species when following plasma growth hormone levels by radioimmunoassays. Furthermore, it has recently been realized that the sequence Val-His-Leu-Ser-Ala-Glu-Glu-Lys-Glu-Ala is similar to a fragment of the beta chain of porcine hemoglobin.[25]

Several laboratories have recently reported[26] obtaining purified extract of hypothalamic tissues that would be endowed of growth hormone releasing activity based on radioimmunoassays, the active material being different (behavior on G-25) from Schally's "GRH." The nature of the active principles in these extracts is unknown at the moment. Thus, the nature of the hypothalamic factors stimulating the secretion of growth hormone remains to be elucidated. Similarly, no reliable evidence is available for the nature of the hypothalamic factors postulated in the control of the release of prolactin (PRF) or ACTH (CRF for corticotropin releasing factor).

The nature of the postulated inhibitory factors for the release of prolactin (PRIF) or for the release of growth hormone (SRIF, for somatotropin-release inhibiting factor) is similarly unknown at the writing of this review.

The tripeptide Pro-Leu-Gly-NH_2, obviously the C-terminal of oxytocin, has been allegedly isolated from hypothalamic extracts and has been proposed as the MSH-release inhibiting factor (MRIF).[27,28] Along the same lines, the pentapeptide H-Cys-Tyr-Ile-Gln-Asn-Cys-OH or tocinoic acid has also been reported in hypothalamic extracts and has been proposed[29] as the primary structure of the postulated MSH releasing factor (MRF). There is a great deal of controversy at the moment about the significance of these two proposals regarding the biological activities attributed to these two

oligopeptides--the controversy being due to the difficulties of the bioassays involved. This, thus, remains for future clarification.

Characterization of these hypothalamic hypophysiotropic hormones has been of major significance in physiology. Availability of the purified TRF and later of pure synthetic TRF led to the demonstration that the well known negative feedback mentioned above between thyroid hormone secretion and TSH secretion is actually taking place at the level of the pituitary tissue in some sort of antagonism between the thyroid hormones and TRF.[30] The molecular biology of this negative feedback is now fairly well understood and appears to involve a polypeptide or protein molecule not characterized so far, induced by thyroxin or tri-iodothyronine within the thyrotrophs of the pituitary; this polypeptide is able to antagonize some secondary event that follows activation by TRF at the level of the thyrotroph's plasma membrane of some biochemical event that normally leads to the secretion of TSH. Several steps of this mechanism in the negative feedback regulation of the secretion of TSH by thyroid hormones and TRF remain to be elucidated.

There is evidence that the steroid hormones (glucocorticoids or sex steroids such as estrogens, progesterone or testosterone) participate in the negative feedback on the secretion of the gonadotropins LH and FSH in a somewhat different manner; while they appear to act also at the level of the pituitary to inhibit quantitatively the pituitary response to LRF in terms of the secretion of LH and FSH, (probably through some mechanism similar to the one involved in the negative feedback of thyroid hormones on TSH secretion) there is also good evidence that the steroids act somehow at the level of the hypothalamus[10,31] to inhibit the secretion of the hypothalamic releasing factor, LRF. The recent availability of synthetic LRF in large quantities will allow further investigation of this physiologically important phenomenon.

If it is eventually and unquestionably demonstrated that hypothalamic extracts do contain hypophysiotropic *inhibitory* substances for the secretion of several of the hypophysial hormones, the neurosecretory neurones of the hypothalamus would thus be shown to partake in the general physiological laws that neurophysiologists have proposed over the last 50 years, namely, that excitatory neurones or fibers have corresponding inhibitory neurones and fibers. The hypothalamic neurosecretory neurones would thus correspond to a highly specialized type of neurosecretory tissue still subjected, however, to the same types of regulatory

and integrative mechanisms that are known to be present throughout the central nervous system. There is good and increasing evidence that the neurosecretory neurones of the hypothalamus respond to specific and classical neurotransmitters such as catecholamines, serotonin, which thus would represent the neurotransmitters specifically mediating endoceptive or exteroceptive stimuli leading to the specific secretion of one or another of the hypothalamic hypophysiotropic hormones.[32,33]

The hypothesis of the existence of specific hypothalamic hypophysiotropic hormones has been, over the last few years, of major significance in the formation of concepts to explain a series of endocrine diseases. Recent availability of TRF and LRF have dramatically confirmed these earlier hypotheses. There are a number of diseases, particularly in children and young adolescents, which for years have been considered to be, possibly, of hypothalamic origin.[34] These are usually related to clinical problems involving deficiencies in functions of the thyroid gland, of the gonads, of statural growth, of adrenal-cortical function. In many cases where one could stimulate the peripheral glands by injection of purified human pituitary hormones, these patients could show a normal response of the peripheral organs, thyroids, adrenal cortex, testes, ovary, or statural growth in response to the pituitary hormones. Thus, their primary defect was not to be found at the level of the peripheral glands or tissues but probably at the level of the pituitary or the hypothalamus. Direct exploration of these two possibilities, *i.e.*, hypothalamic defect versus pituitary defect, was not possible, except by some relatively complicated indirect means of only circumstantial significance until availability of TRF and LRF. It is now well recognized that these patients can be divided into major groups in accordance to their pituitary responses to injection of the hypothalamic releasing factors. Either they do respond normally to injection of TRF or LRF--in which case their primary defect is obviously not in their pituitary but most likely at the level of their hypothalamus, or they do not respond to injection of TRF or LRF--their primary lesion or defect being thus at the level of the pituitary. A number of cases have thus been recently described in which abnormality of the response of these patients to either TRF or LRF led to further investigation of the status of their pituitary function; in a large number of such cases, evidence was observed for the existence in these patients of pituitary tumors which probably would not have been suspected on the basis of clinical observations at the time at which the patients were seen.[35]

A number of children have been known for the last few years to present what is called isolated pituitary deficiency or monotropic hypopituitarism, that is a series of syndromes in which, somehow, one pituitary hormone seems to be missing in the pituitary secretion; this has been observed for TSH, for ACTH, for LH and/or FSH and for growth hormone. Since the secretion of the other pituitary hormones appears to be normal in those children, the question was raised as to whether their defect would be pituitary or hypothalamic. There is now good evidence that, in most of these children, one can stimulate specifically the secretion of the missing pituitary hormone by administering the hypothalamic releasing factor. Obviously, in these children, the primary defect is hypothalamic, Other children with this same syndrome do not appear to respond to the hypothalamic hormone; their primary defect is thus at the level of the pituitary tissues. Replacement therapy in the human with pituitary hormones requires that only hormones of human origin be administered, with the exception of ACTH. Human gonadotropins, or growth hormone, or thyrotropin are indeed endowed of strict species specificity likely related to their complicated structures; ACTH, being a simpler polypeptide, is not species specific. Thus, when one considers the possibility of replacement therapy in these children, one must have available for years of treatment, large quantities of human pituitary hormones. Only small quantities of pituitary glands of human origin are available for preparing human pituitary hormones for clinical use. On the other hand, since the hypothalamic releasing factors can be easily synthesized in unlimited quantity and since the known sequences correspond to molecules highly active in the human, TRF and LRF are already used extensively in clinical medicine as diagnostic tools and also as therapeutic agents for chronic treatment of the pertinent deficiencies in children.[36]

Of extreme interest will be the availability of a growth hormone-releasing factor and also of the postulated growth hormone release-inhibiting factor. By far, the largest number of these children with these hypothalamic-hypophysial defects seem to suffer from deficiencies in the secretion of growth hormone. There is also a syndrome which has been described of emotionally disturbed children with stunted growth. Assuming that the pituitary secretory ability of these children for growth hormone is normal, the treatment of choice for them would be the chronic administration of the synthetic peptide with growth hormone-releasing activity while the cause of their behavioral problem is being removed. Growth hormone release inhibiting

factor would also be of major clinical significance in the large population of adolescents suffering of what is known as juvenile diabetes. Current concepts implicate somehow the endogenously secreted growth hormone in those patients in the triggering and the evolution of their usually malignant diabetes.[37] Hypophysectomy is presently the only and, unfortunately, drastic treatment for these children. It is logical to assume that availability of a growth hormone release-inhibiting factor should be of clinical value in the treatment of their disease. Similarly, a not infrequent disease known as acromegaly, in which the pituitary secretes abnormally high amounts of growth hormone, should be alleviated by administration of a growth hormine release-inhibiting factor.

The hypothalamic LH releasing factor administered acutely in humans stimulates dramatically the secretion of gonadotropins in men and women (Figure 6).[38,39] There is early

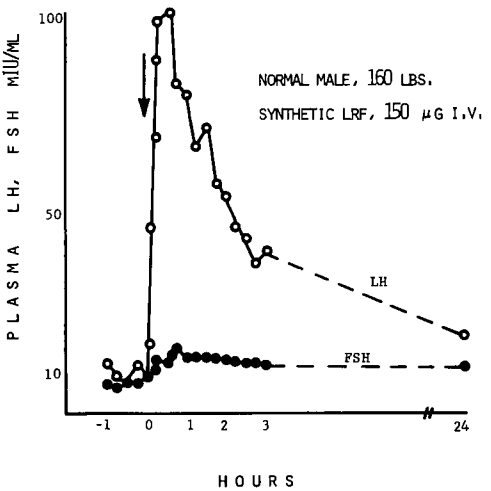

Figure 6: Stimulation of the secretion of the gonadotropins LH and FSH in a normal human male by a single intravenous injection of synthetic LRF. Plasma LH and FSH measured by radioimmunoassay. (In collab. with S. Yen, U. of California, San Diego)

evidence that one can trigger ovulation in women who have suffered of what has been known for years as hypothalamic amenorrhea or infertility. The hypothalamic decapeptide LRF is the treatment of the infertility of these women. There is increasing evidence that chronic administration of the hypothalamic decapeptide LRF can also reestablish

to normal the testicular function of several types of oligospermia for which no evident etiology was known and which thus, may be of hypothalamo-hypophysial origin. If LRF can stimulate ovulation in women, there is good reason to believe that it could be used as an exogenous agent to regulate the ovarian cycle and induce ovulation at a precise time in some sort of a rhythm method that could thus be used as an acceptable means of fertility control in some cultures.

There is also the possibility that analogues of LRF endowed of antagonistic activities to LRF--such molecules have recently been reported in the literature[40] and shown to be active as antagonists of LRF in experimental animals--could be used as a novel approach to fertility control. Availability of antagonists to endogenous LRF may lead to a once-a-month type of medication that could be used as a contraceptive.

Demonstration of the existence of the hypothalamic hypophysiotropic hormones and the recent characterization of several of them have, undoubtedly, opened a new chaper in physiology and in modern medicine. I think that the physiologists and the biochemists who have made these discoveries can take added pride in the fact that once more research, originally directed at problems of purely fundamental, of "academic" significance, is leading to practical solutions in clinical medicine.

CHEMISTRY AND BIOLOGY OF PEPTIDES

STRUCTURE-BIOLOGICAL ACTIVITY RELATIONSHIPS ON THYROTROPIN AND LUTEINIZING HORMONE RELEASING FACTOR ANALOGUES

M. Monahan, J. Rivier, W. Vale, N. Ling, G. Grant, M. Amoss, R. Guillemin, R. Burgus. The Salk Institute, La Jolla, California 92037

E. Nicolaides, M. Rebstock. Parke-Davis Company, Ann Arbor, Michigan 48105

MANY ANALOGUES OF TRF (thyroid stimulating hormone releasing factor) have been synthesized and tested biologically and from this information, several generalizations can be drawn regarding structure-function relationships. Most of the data presented here on TRF have been reviewed previously[1] and we will present some ideas about the chemical interpretation of these results.

TRF analogues were examined for purity by tlc (at least four systems), amino acid analysis, mass spectral and NMR analysis. All were judged homogeneous by these criteria with the exception of III, XVII, XXII, XXIV and XXXI which exhibited trace impurities on tlc at a 20 μg load. Compounds IV and V were tested as crude unresolved mixtures [these two compounds were synthesized with the racemic pyroglutamic acid (<Glu) analogues].

Changes at the <Glu^1 position of TRF result in a considerable decrease in ability to induce secretion of thyroid stimulating hormone (TSH). Nevertheless, there are marked differences in the [R^1]-TRF analogues tested (Table 1). These data suggest that the N^{α} of <Glu is involved as a nucleophile in the action of TRF. An N^{α}-methyl function on <Glu could introduce allosteric interference at the receptor-substrate complex level, or it could interfere with a nucleophilic process involving the N^{α} of <Glu. Of possible

significance to the latter interpretation are the relative activities of compounds IV, V and VI when compared to the relative nucleophilicities of S, O, and C. Compound III, ([Pro^1]-TRF) ought to be more reactive than these three compounds, except that the N^{α} of Pro is protonated at physiological pH, which would reduce its utility as a nucleophile.

Histidyl modifications involving charged groups reduce the biological activity considerably (compounds VII, VIII and IX). However, there appears to be a rigid requirement for aromaticity at this position as shown by the high activity (10%) of [Phe^2]-TRF.[2] The marked difference in activity between this compound and [Tyr^2]-TRF might be explained in terms of steric interactions in the receptor-substrate complex. [Met^2]-TRF retains substantial activity, although less than the aromatic substitutions, except for [N^{π}-Me-His^2]-TRF. CPK models indicate that the side chain of methionine fills almost the same space as the side chain of histidine with the sulfur atom able to occupy nearly the same position as the imidazole π-nitrogen. It is possible that both aromaticity and a general acid function are required of the imidazole of histidine. Pertinent to the latter point is the observation that [N^{π}-Me-His^2]-TRF has a very low biological potency while [N^{τ}-Me-His^2]-TRF is eight times more active than the parent molecule. However, other factors could also explain these results (conformational orientation, steric interactions, *etc.*).

Measurements of the pKa of the imidazole of histidine in several TRF analogues[3] reveal that the pKa and biological potency appear to correlate (Figure 1 and Table I). Two points on this plot which fall outside the curve represent compounds which are ionized at physiological pH. Formal charges on the molecule reduce the biological potency considerably. The relationship between pKa and potency supports the hypothesis that the histidine side chain may be involved as a general acid.

Prolinamide substitutions can involve retention of considerable potency. An amide substituent can easily assume a conformation whereby it does not interfere with other groups in the remainder of the molecule (or alternatively, the same could be suggested for interactions in the receptor-substrate complex). Tertiary amides are much less active than the potent secondary amides. The presence of a charged group (compound XXI) at the C-terminus yields a drastic reduction in activity when compared to hydrophobic amide substitutions.

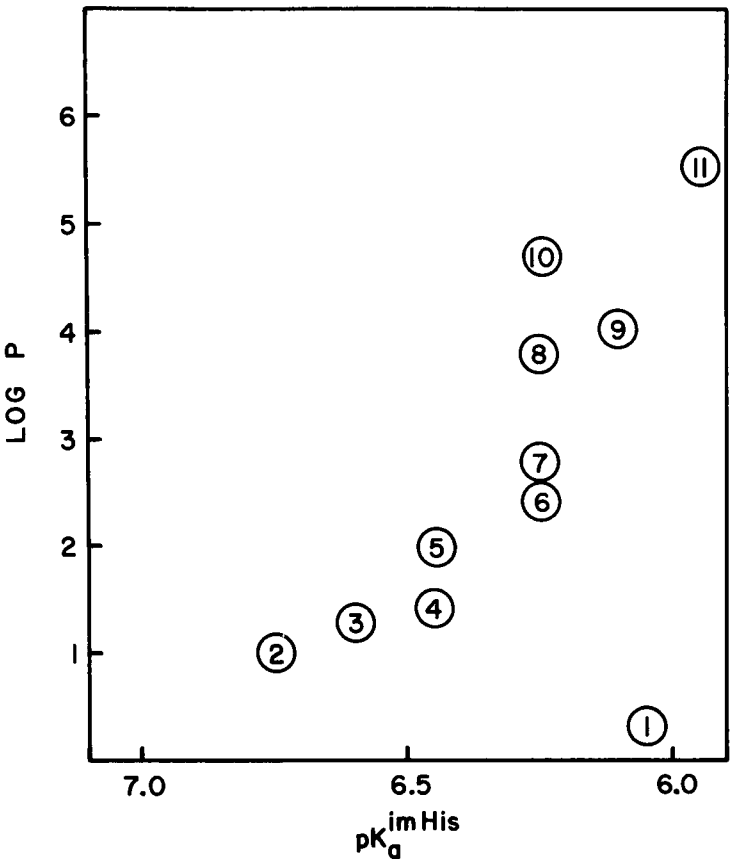

Figure 1: Logarithm of biological potency (P) *vs.* pKa of the imidazole of histidine. Numerical designation of points corresponds to roman numerals in Table I: 1 (III); 2 (XXI); 3 (XIII); 4 (XXX); 5 (XXXI); 6 (XXIX); 7 (II); 8 (XXIV); 9 (XX); 10 (I); 11 (XII).

Summarizing the TRF results, we conclude that: The molecule must be hydrophobic; rigid stereochemical or bulk properties must be met for each residue; <Glu may act in a nucleophilic capacity; histidine may be involved as a general acid; and amide substitutions retain high potency except for charge groups or groups of large bulk. It is not surprising that TRF may exhibit poly-functionality (*e.g.*, nucleophilic participation by <Glu and histidine

acting as a general acid), considering the remarkable potency and specificity of such a small peptide.

We have synthesized a variety of analogues of luteinizing hormone releasing factor (LRF, <Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2). All LRF analogues were synthesized on a benzhydrylamine resin by standard solid-phase techniques. Purification, following cleavage in HF, was carried out in two steps: Cation exchange chromatography or gel filtration followed by partition chromatography. Resulting products were analyzed for purity by tlc (seven systems, 20 μg load), amino acid analysis, NMR spectra, mass spectra (heptapeptide or shorter), and optical rotation. Included in these are the peptide amides shortened from the C-terminus, Table II. They are essentially inactive except for des-Gly^{10}-LRF (11%) and the tripeptide <Glu-His-Trp-NH_2 (<0.1%). The LRF analogues involving substitution of glycine for the other residues exhibit potencies of *ca.* 0.1% of LRF activity except for [Gly^4]-LRF (1.5%). Even though [Gly^2]-LRF has a measurable potency as an agonist, it does not exhibit the same dose-response curves as the other analogues and is also a partial inhibitor of LRF. At saturation doses, it yields an intrinsic activity of about 50% that of LRF while saturation doses of the other analogues release LH at the same levels as the saturation doses of LRF. Des-His^2-LRF does not release LH at any of the doses tested *in vitro* and also inhibits LRF making it an even better inhibitor. [Gly^3]- and [Ala^3]-LRF are essentially inactive but are not antagonists. [Phe^2]-, [Phe^3]-, [N^{τ}-Me-His^2]-, and [N^{π}-Me-His^2]-LRF are all active to about the same extent which suggests that aromaticity is a requirement in these positions. It is significant that the methylhistidine substitutions do not yield results analogous to those obtained with TRF.

Even though LRF is more complicated than TRF, the outlook is encouraging in the study of structure-function relationships of LRF. Methods of synthesis of oligopeptide analogues and bioassay methods for their biological activities are relatively rapid and ought to generate considerably more data in the near future. This will lead to a better molecular interpretation of the physiology-biochemistry of this biologically important molecule.

Table II

Luteinizing Hormone Releasing Factor Analogs

Compound	*% LRF Potency**
<Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2	100
<Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-NH_2	10
<Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-NH_2	<0.01
<Glu-His-Trp-Ser-Tyr-Gly-Leu-NH_2	<0.01
<Glu-His-Trp-Ser-Tyr-Gly-NH_2	<0.01

<Glu-His-Trp-Ser-NH_2	<0.01
<Glu-His-Trp-NH_2	<0.01
<Glu-His-NH_2	<0.01
[CH_3CH_2-C(=O)-Gly^1]-LRF	0.2
[Gly^2]-LRF	*
[Gly^3]-LRF	<0.001
[Gly^4]-LRF	1.5
[Gly^5]-LRF	0.1
[Gly^7]-LRF	0.2
[Gly^8]-LRF	0.1
[Gly^9]-LRF	0.2
des-His^2-LRF	<0.001
[Phe^2]-LRF	4
[N^{π}-Me-His^2]-LRF	2
[N^{τ}-Me-His^2]-LRF	6
[Ala^3]-LRF	<0.001
[Phe^3]-LRF	2
[Ala^6]-LRF	1

*Materials having special significance are routinely resynthesized and retested. We originally observed higher potencies for some of the analogues entered in Table II: The first batch of <Glu-His-Trp-NH_2 was observed to have 0.1% LRF potency. In a second preparation, it exhibits activity at a lower potency (*ca.* 0.002%).

CHEMISTRY AND BIOLOGY OF PEPTIDES

COMPLETE AMINO ACID SEQUENCE OF PORCINE β-LIPOTROPIC HORMONE (β-LPH)

Claude Gilardeau, Michel Chrétien. Laboratoire des Protéines et des Hormones Hypophysaires, Institut de Recherches Cliniques de Montréal

WE HAVE ALREADY SHOWN that porcine beta-lipotropic hormone is a single chain protein of 91 amino acids and of molecular weight 9650, with glutamic acid at its NH_2-terminus.[1] Since then we have obtained the complete primary structure. For this work, we have cleaved the molecule at its two methionine residues with cyanogen bromide in 0.1 *N* hydrochloric acid as solvent. This reaction gave, after chromatography on CM-cellulose, five fragments corresponding to residues 1-47, 48-65, 66-91, 1-65, and 48-91. The Edman degradation,[2] using a Beckman sequencer, was performed on the entire molecule and on these fragments. The first 83 amino acid residues, except 79 and 80, could be deduced. The remaining amino acids were placed after enzymic degradations.

Peptide 66-91 was cleaved with chymotrypsin and yielded two main products after purification by paper electrophoresis in collidine acetate buffer and paper chromatography in BPAW: one peptide (C_1) contains residues 66-78 and the other (C_2), residues 79-91. This last peptide contains 4 lysines, and has a lysine at its NH_2-terminus, as determined by dansylation. It was digested with trypsin and gave the peptides in Table I.

Peptide C2T2 (80-84) has the sequence Asn-Ala-Ile-Val-Lys since Ala-Ile-Val was determined by the sequencer and since Asn was found to be the NH_2-terminal residue from dansylation and leucine amino peptidase.

Table I

Amino Acid Analysis of Fragments From Tryptic Digestion of Peptide C2

C2T1	Asp, Ala, His, Lys, Lys
C2T2	Asp, Ala, Ile, Val, Lys
C2T3	Gly, Glu

Only residues 85-91 remained unknown. These correspond to peptides C2T1 and C2T3. Dansylation of peptide C2T1 gave aspartic acid; and leucine amino peptidase cleaved mainly Asn and Ala after 8 hours of incubation. The sequence proposed is: Asn-Ala-(His-Lys)-Lys.

The COOH-terminal residue of beta-LPH, as determined by carboxypeptidase A digestion, is glutamine. Equimolar amounts of glycine and lysine were also released in much smaller quantities than glutamine after 24 hours of incubation. Since peptide C2T3 contains Gly-Gln, the COOH-terminus must be Lys-Gly-Gln; and since there is almost no histidine released by carboxypeptidase A, there must be two consecutive lysines at positions 88-89.

From these data, the following sequence is proposed:

Glu-Leu-Ala-Gly-Ala-Pro-Pro-Glu-Pro-Ala-Arg-Asp-Pro-Glu-Ala-
5 10 15
Pro-Ala-Glu-Gly-Ala-Ala-Ala-Arg-Ala-Glu-Leu-Glu-Tyr-Gly-Leu
20 25 30
Val-Ala-Glu-Ala-Glu-Ala-Ala-Glu-Lys-Lys-Asp-Glu-Gly-Pro-Tyr-
35 40 45
Lys-Met-Glu-His-Phe-Arg-Trp-Gly-Ser-Pro-Pro-Lys-Asp-Lys-Arg-
50 55 60
Tyr-Gly-Gly-Phe-Met-Thr-Ser-Glu-Lys-Ser-Gln-Thr-Pro-Leu-Val-
65 70 75
Thr-Leu-Phe-Lys-Asn-Ala-Ile-Val-Lys-Asn-Ala-His-Lys-Lys-Gly-
80 85 90
Gln.

Comparison of this sequence with the revised amino acid sequence of sheep beta-LPH,[3] Table II, shows that twelve amino acid residues are different; this number may change, since the revision of sheep beta-LPH was only on the first 38 residues.

Table II

Comparison Between the Amino Acid Sequences
Of Porcine and Sheep Beta-LPHs

CHEMISTRY AND BIOLOGY OF PEPTIDES

STRUCTURE AND FUNCTION OF ADRENOCORTICOTROPIN: EFFECTS OF THE *O*-NITROPHENYL SULFENYL DERIVATIVE OF THE HORMONE ON ISOLATED RAT ADRENAL CELLS

J. Ramachandran, W. R. Moyle, Y. C. Kong. The Hormone Research Laboratory, University of California, San Francisco, California 94122

DURING THE COURSE OF STUDIES of the structure-function relationships of adrenocorticotropin (ACTH), it was observed that chemical modification of the single tryptophan residue in the molecule by reaction with *o*-nitrophenylsulfenyl (Nps) chloride produced profound changes in the extra adrenal actions of the hormone.[1-3] Nps-ACTH was found to inhibit the ACTH induced stimulation of lipolysis in rat fat cells.[1] On the other hand, Nps-ACTH was more potent than ACTH in stimulating lipolysis in rabbit fat cells and in darkening amphibian skins[2] (melanocyte stimulating activity). Nps-ACTH inhibited the ACTH induced stimulation of adenylate cyclase in rat fat cell ghosts[3] as well as in rat adrenal homogenate fractions.[4] In order to elucidate the role of the tryptophan residue in the adrenal stimulating actions of ACTH, the effects of Nps-ACTH on steroidogenesis and cyclic AMP accumulation in isolated rat adrenal cells was investigated.

ACTH and Nps-ACTH were incubated with cells isolated from rat adrenals by digestion with collagenase.[5] The production of corticosterone was monitored by a fluorometric method[6] and cyclic AMP generation was measured by the protein binding method of Gilman.[7]

From Figure 1 it is evident that both ACTH and Nps-ACTH stimulate steroidogenesis to the same extent, although higher concentrations of Nps-ACTH are required. The concentration of Nps-ACTH required for half-maximal steroidogensis was approximately seventy times that of ACTH (Table I) indicating

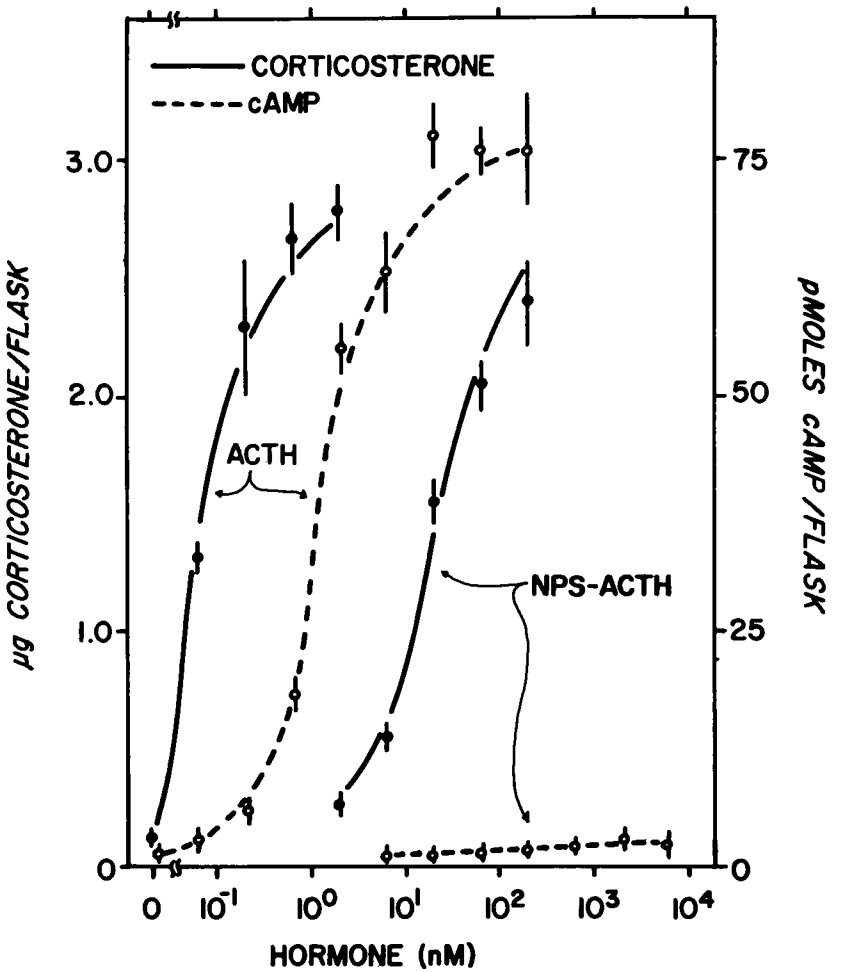

Figure 1: Stimulation of corticosterone synthesis and cyclic AMP accumulation in isolated rat adrenal cells in response to ACTH and Nps-ACTH.

an apparent decrease in the affinity of the hormone due to modification of the tryptophan. On the other hand, Nps-ACTH stimulated cyclic AMP accumulation marginally (3% of that due to ACTH). In addition, Nps-ACTH inhibited competitively the effect of ACTH on cyclic AMP accumulation. It was estimated from the inhibition studies that the apparent K_I for Nps-ACTH was nearly equal to the concentration of ACTH

Table I

Concentrations of ACTH and Nps-ACTH Required for the Stimulation of Steroidogenesis and Cyclic AMP in Isolated Adrenal Cells

Hormone	*Steroidogenesis**	*Cyclic AMP synthesis†*	*Inhibition of cyclic AMP synthesis#*
ACTH	0.51	3.6	
Nps-ACTH	34	39	3.8 - 5.1

The values shown refer to the average nano molar concentration of ACTH or Nps-ACTH required to produce half-maximal stimulation of corticosterone synthesis or cyclic AMP formation.

*Both ACTH and Nps-ACTH stimulated steroidogenesis to the same maximum.

†Nps-ACTH produced less than 3% of the stimulation of cyclic AMP formation produced by ACTH at maximal effective concentrations.

#Apparent K_I.

required for half-maximal stimulation of cyclic AMP production, indicating that Nps-ACTH and ACTH have the same affinity for adrenal cells. These results suggest that the integrity of the tryptophan residue is essential for maximal cyclic AMP formation in adrenal cells but not for maximal steroid synthesis. Since cyclic AMP is considered to be the intracellular messenger mediating all the actions of ACTH,[8] the increase in intracellular cyclic AMP concentration required for the steroidogenic response must represent a very small fraction of the total increase in cyclic AMP concentration produced in response to ACTH. An alternative explanation of the results presented here would be that an unknown factor(s) besides cyclic AMP is involved in mediating the action of ACTH at low concentrations.

The apparently contradictory results obtained with Nps-ACTH, namely a decrease in the affinity of the hormone indicated by the higher concentrations required for stimulating steroidogenesis, and no change in affinity indicated by the inhibitory effect on cyclic AMP accumulation, can be

accounted for on the basis of two types of receptors for ACTH in the adrenal cells. Modification of the tryptophan residue may have affected the interaction of the hormone with the two affinity sites differently. These results can also be explained according to the concept of spare receptors.[9] According to this ACTH is able to stimulate maximal steroidogenesis by interaction with only a small per cent of the available receptors. Nps-ACTH must occupy nearly all the available receptors to generate sufficient cyclic AMP for the stimulation of steroidogenesis.

CHEMISTRY AND BIOLOGY OF PEPTIDES

CYCLIC AMP AND THE MECHANISM OF ACTION OF GASTROINTESTINAL HORMONES

M. Samir Amer, Gordon R. McKinney. Department of Pharmacology, Mead Johnson Research Center, Evansville, Indiana 47721

ALTHOUGH CYCLIC AMP HAS BEEN convincingly shown to mediate the actions of a large number of hormones, its role in the mechanism of action of most gastrointestinal hormones is not clear. Studies from this laboratory indicated that gastrin, cholecystokinin and related peptides and insulin stimulate cyclic AMP phosphodiesterase (PDE) in their target tissues in the rabbit, Table I. Stimulation of PDE was brought about in every case by a shift in activity from a soluble, high Km (low affinity) to a low Km (high affinity), and possibly particulate, form of the enzyme. The effects of these hormones on PDE would be expected to result in a decrease in the intracellular levels of cyclic AMP as was shown to be the case with insulin in liver and cholecystokinin in the gall bladder. Thus it would seem that stimulation of PDE is a common mechanism for the action of a number of gastrointestinal hormones to lower the intracellular levels of cyclic AMP. This is in contrast to the actions of secretin and glucagon in elevating intracellular cyclic AMP levels via stimulation of adenylate cyclase. Thus PDE may be a site for hormonal regulation of cyclic AMP levels rather than a switch for termination of cyclic AMP effects.

A careful examination of the literature relating cyclic AMP to gastric secretion indicates that this mechanism may also mediate the effects of these hormones on gastric secretion and that gastric secretion, if mediated by cyclic AMP, is triggered by a decrease rather than an increase in

TABLE I

Interrelationships of Various Factors, Cyclic AMP and Gastric Secretion

the intracellular concentrations of the cyclic nucleotide. Table I summarizes the effects of a large number of agents on gastric secretion and their known or expected effects on cyclic AMP levels. It is clear from the table that an inverse relationship exists between cyclic AMP levels and gastric secretion and smooth muscle tone. The notable exception is in the case of methylxanthines which do have other effects on mucosal blood flow and permeability to Ca^{++} that can account for their unexpected, stimulatory effects on gastric secretion.

Stimulation of PDE may therefore mediate the gastric-stimulatory effects of gastrointestinal hormones. It further provides the basis of the inhibitory effects of secretin and glucagon on gastric secretion and their antagonism to the stimulatory effects of gastrin, cholecystokinin and related peptides.

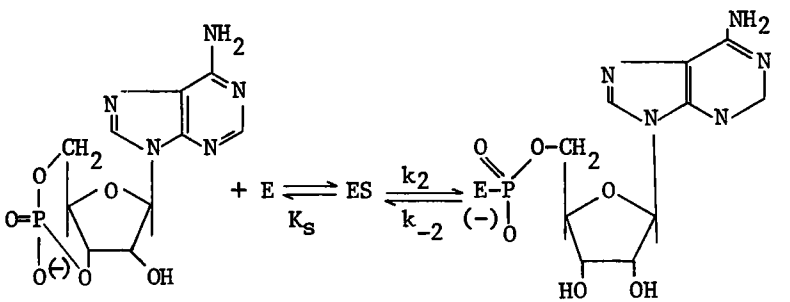
CHEMISTRY AND BIOLOGY OF PEPTIDES

PROPOSED MECHANISMS OF ACTION OF 3', 5'-CYCLIC AMP, SOME CYCLIC PEPTIDES AND RELATED COMPOUNDS

G. Moll, E. T. Kaiser. Departments of Biochemistry and Chemistry, University of Chicago, Chicago, Illinois 60637

THE SIX-MEMBERED CYCLIC PHOSPHATE DIESTER 3',5'-cyclic AMP is thought to act as a second messenger in the action of many hormones.[1] The possibility that cyclic AMP may owe its effectiveness as a messenger in hormone action to its potential ability to phosphorylate enzymes reversibly in a manner similar to that described earlier for the "autore-generative" interaction of the highly strained cyclic phosphate diester, catechol cyclic phosphate,[2] with chymotrypsin is under investigation in our laboratory. The generalized reaction pathway we postulate for the interaction of cyclic AMP with enzymes is illustrated in Equation 1 below. Cyclic AMP may react with enzymes either



(1)

at their active sites or at regulatory sites with concomitant ring-opening to produce covalent phosphoryl-enzyme species.[2,3] Under appropriate conditions where kinetic control is favored, the hydroxyl group produced by ring-opening which remains covalently bound in close proximity to the phosphoryl function can act as an intramolecular nucleophile, attacking the phosphorus, blocking the attack of water (which would cause the destruction of cyclic AMP), and causing the re-formation of cyclic AMP with the release of free enzyme. The relative concentrations of the species involved in the equilibria of Equation 1 should be affected by changes in pH, perhaps because of changes in the ionization state of important enzyme functional groups, and by other factors such as metal ion concentrations. Thus, it can be seen how cyclic AMP could regulate the action of many enzymes in a very effective way.

We have performed experiments on the denaturation of bovine skeletal muscle protein kinase in the presence of labeled cyclic AMP which indicate that a substantial amount of the labeled material remains bound to the enzyme even after denaturation. In addition, our studies on the enzymatic digestion of the complex formed between cyclic AMP and bovine brain protein kinase can be best accounted for in terms of the covalent binding of cyclic AMP to the enzyme as postulated in the scheme of Equation 1.

The analogy between the proximity effects of the newly generated hydroxyl groups produced by reactions like that shown in Equation 1 and the effect of the amino group of the newly formed amino terminal acid present in the acyl-trypsin resulting from the interaction of soybean trypsin inhibitor and trypsin has been noted.[4,5]

Proceeding further, we have been considering the possibility that various cyclic peptides, peptides containing lactam rings, or related compounds, may exert their influence on biological reactions by processes similar to those indicated in Equation 1 above. This is illustrated in Equation 2 where the hypothetical interaction of thyrotropin-releasing hormone[6] with a protein receptor is considered. According to this hypothesis, the lactam ring present in the hormone is cleaved on reaction with a protein receptor, generating an acylated protein and releasing an amino group which remains in proximity to the acyl function and maintains the equilibrium between the intact hormone and unmodified protein species on the one hand and the modified protein on the other.

SYMPOSIUM DISCUSSIONS

Summarized by Johannes Meienhofer

HYPOTHALAMIC PEPTIDES continue to be a topic of very great interest, and the difficulties in identifying and isolating these hormonal control factors are not only due to their minute quantities in tissues, but also to bioassay problems. A discourse on the melanotropin (MSH)-release inhibiting factor,[1-3] MIRF, centered around complications with bioassays in frogs or toads itself and with comparing data from different laboratories. Both the *C*-terminal tripeptide of oxytocin, Pro-Leu-Gly-NH_2, and the ring moiety, tocinoic acid, have been implicated as inhibiting agent, and the *N*-terminal pentapeptide, Cys-Tyr-Ile-Gln-Asn, has been proposed as possible releasing factor. A question was raised about bioassay data on synthetic analogs of luteinizing hormone releasing factor (pp 601 to 608) which range in potency over 4-5 orders of magnitude. Concern about activities in the range of 0.001% to 0.005% pertains not only to the significance of differences between analog activities in that range, but also to the homogeneity of these decapeptides that have been synthesized by solid-phase procedures. A preparation only needs to contain 0.1% of an impurity (failure sequence, derivative, diastereoisomer, etc.) possessing 1% of the potency of LH-RH to exhibit 0.001% of activity. In reply to some questions it was pointed out that, in general, dose-response curves showed the same slope except for those analogs with inhibitory action, and that the ratios of LH-RH to FSH-RH activities remained constant in all analogs tested. The significance of the C-terminal amide, common to hypothalamic factors, along with the pyroglutamyl N-terminus, was discussed. It might be a protective factor (to get through membranes in a certain way, or to be

resistant to enzymes), or it might indicate certain possible biosynthetic origins (Gross, pp 671 to 678).

A question was raised whether the β-lipotropic hormone could actually be regarded as a "hormone." In reply, it was pointed out that a related polypeptide from sheep pituitaries had been shown some time ago to possess activity on rabbit and rat fat cells;[4] apparently no further bioassays have yet been done on porcine β-LPH (pp 609 to 611).

The report on the effects of the *o*-nitrophenylsulfenyl derivative of ACTH aroused a lively discussion centering around the use of isolated adenyl cyclase, the levels of cyclic AMP employed in this work, and the possibility of increased metabolism of cyclic AMP by phosphodiesterase as a cause of its disappearance. Several arguments developed about proposed new mechanisms of action of cyclic AMP (Kaiser, pp 621 to 623).

CHEMISTRY AND BIOLOGY OF PEPTIDES

THE PRECISION AND SENSITIVITY OF AMINO ACID ANALYSIS

Stanford Moore. The Rockefeller University, New York, New York 10021

SUMMARY--Amino acid analysis bears a relationship to the chemistry of proteins and peptides similar to that which elementary analysis bears to the chemistry of simpler organic molecules. The subject is reviewed in terms of the resolution achievable by automatic ion exchange chromatography, the variations in the speed of the analysis, the range in sample size from 1 micromole to 1 nanomole, methods of integration, and the precision obtainable under practical conditions. With well-standardized instruments and optimum resolution, 3% is a reasonable maximum deviation from theory in the recovery of pure amino acids in a single run; the borderline separation with some 2-hour methodologies raises the maximum error to about 5%.

This precision does not include the errors inherent in the hydrolysis of the protein or the peptide to the constituent amino acids. With 6 *N* HCl at 110° the small losses of serine and threonine can be corrected for with adequate precision; cystine or cysteine can be most precisely determined after derivatization. Tryptophan, which is labile in HCl, is a special case which has led to the finding that methanesulfonic acid may be generally preferable to HCl for acid hydrolysis. Alkaline hydrolysis is the only method that provides quantitative recoveries of tryptophan when carbohydrates are present in the sample. D- and L-amino acids can be determined by chromatographic separation of the diastereoisomeric dipeptides obtained by condensation with L-leucine or L-glutamic acid *N*-carboxyanhydride.

Examples are given of the approach to integral molar ratios of amino acids obtainable in routine analyses of chromatographically purified peptides.

INTRODUCTION--THE SUBJECT OF THIS CONTRIBUTION was suggested by Ralph Hirschmann. In thinking about the plans for this symposium, he felt that it would be practical to have a discussion of how close to theory one can expect to come in the amino acid analysis of a pure synthetic peptide. Or, alternatively, to what extent does a given departure from theory indicate impurity in the peptide or possible errors in the analysis? We will attempt to answer these questions in terms of current practice.

With a small synthetic peptide C, H, and N analysis is a valuable criterion in the characterization of the preparation. . .

Carbobenzoxy-leucyl-alanine methyl ester:[1]

$C_{18}H_{26}N_2O_5$.	Calculated	C 61.71	H 7.45	N 8.00
	Found	C 61.64	H 7.37	N 8.17

The long history of organic microanalysis provides the chemist with guidelines on how close he can expect to come to theory. But with large peptides, such as bovine pancreatic ribonuclease, a recent subject of synthesis,[2-4] elementary analysis for C, H, and N remains desirable but is less informative and the molecule is best studied in terms of the component amino acids, in terms of the 124 amino acid residues of (in this instance) seventeen types.

Bovine pancreatic ribonuclease A:[5,6]

$C_{587}H_{909}O_{197}N_{171}S_{12}$

$Asp_{15}Glu_{12}Gly_3Ala_{12}Val_9Leu_2Ile_3Ser_{15}Thr_{10}Met_4$-
$Pro_4Phe_3Tyr_6His_4Lys_{10}Arg_4 1/2\ Cys_8Amide(NH_3)_{17}$

In elementary analysis errors can arise from inadequacies in the combustion or the digestion and in the measurement of the end products. Similarly, in amino acid analysis, the sources of error are in the hydrolysis of the peptide chain and in the determination of the resulting individual amino acids. First let us consider the precision with which the amino acids can be separated and measured and then turn to the problems inherent in the preliminary step of hydrolysis.

Automatic Amino Acid Analyzers

Present automatic amino acid analyzers owe their genesis to the renaissance in chromatography stimulated by Martin and Synge. If we had to follow the tradition of elementary analysis and use specific procedures for each amino acid, the analysis of a protein would be a very tedious and time consuming process, as it was for Erwin Brand's[7] analysis

of β-lactoglobulin in 1946. Chromatography gave promise of providing a physical method which would separate all of the amino acids of a protein hydrolysate by a single technique. In the 1940's William Stein and I undertook to develop starch columns with alcohol-water eluents[8,9] into a system which would give quantitative recovery of each amino acid added to the column (Figure 1). We are not

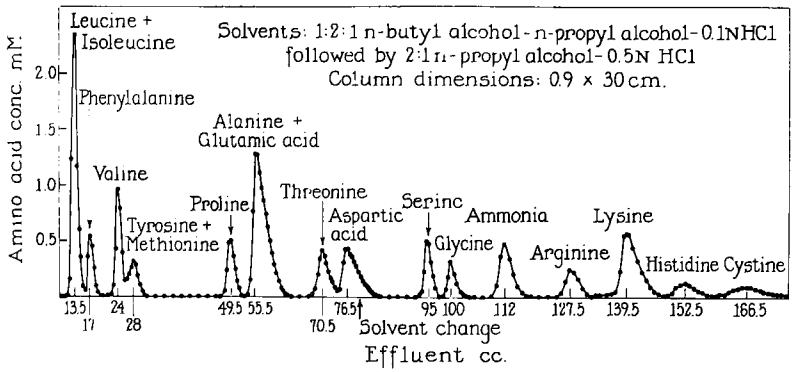

Figure 1: Chromatography of a hydrolysate of bovine serum albumin on a starch column with butyl alcohol-*n*-propyl alcohol-aqueous HCl solvent systems (1949).[10] The sample corresponded to about 2.5 mg of protein.

going to burden you with much ancient history in this introduction, but it is encouraging to note how, over the years, the results from many academic and industrial laboratories have speeded up the process of amino acid chromatography. When we obtained, in 1949, the type of quantitative chromatogram[10] shown in Figure 1, with about 1 micromole of amino acid per peak, we were very happy to be able to analyze a protein hydrolysate in about ten days by running three such columns to resolve all overlaps. The main features of this type of experiment were the collection of effluent fractions of precise volume[8] by an automatic fraction collector (Figure 2) and photometric measurement of the concentrations of the amino acids by a quantitative version[11-13] of the ninhydrin reaction (Figure 3), the product from α-NH_2 acids being read at 570 mμ and those from proline and hydroxyproline at 440 mμ. In the 1950's William Stein and I speeded the process up to a five-day run (Figure 4) by turning to ion exchange

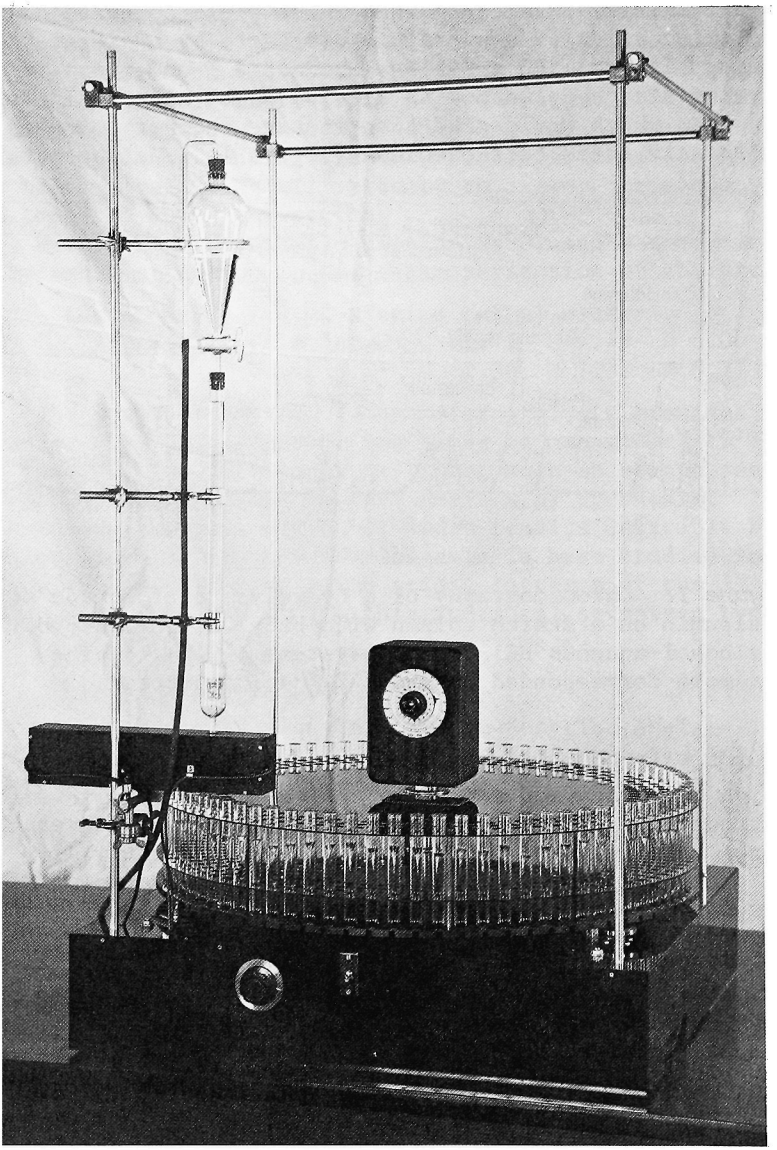

Figure 2: Automatic fraction collector for chromatographic analysis with volume control by the counting of drops (1948).[8]

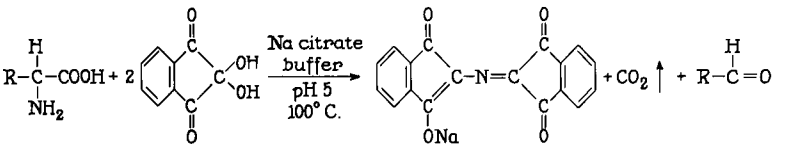

Figure 3: The reaction of ninhydrin with α-amino acids as applied in the quantitative photometric analysis[11-13] of eluents from chromatograms.

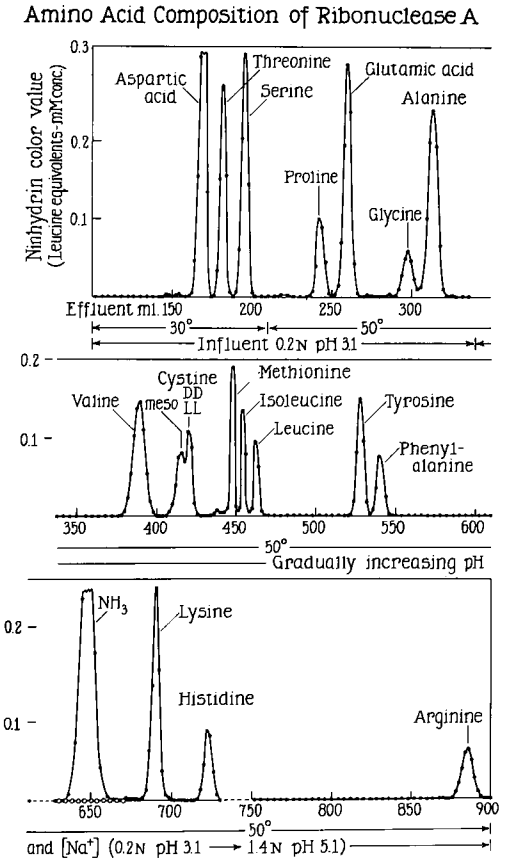

Figure 4: Chromatographic analysis of a hydrolysate of 2 mg of bovine pancreatic ribonuclease A[16] on a 150 x 0.9 cm column of Dowex 50-X4 (1954).[15]

chromatography[14,15] on 9 mm bore columns of sulfonated polystyrene resin. By the 1960's, in cooperation with Darrel Spackman, the process was automated[17] (Figure 5) to give recorded curves, and (Figure 6) the speed was increased[17,18] to provide an overnight run with 150 and 50 cm columns.

In reference to Figure 6 we should mention the reserve resolving power represented by the spaces between the peaks on that chromatogram. When you analyze a synthetic peptide, you have a fair idea of what amino acids to expect; you can be reasonably sure that ninhydrin-positive material eluted near the lysine position is lysine. But with naturally occurring peptides and proteins there are additional constituents to consider; for example, histones contain N^{ε}-methyllysines,[19] actin and myosin contain 3-methylhistidine,[20] and many microbial peptides (*e.g.* edeine[21]) have unusual amino acids. As we turn to shorter columns, which can be adequate for peptides or proteins of known qualitative composition, we need to keep in mind that the analysis is no sounder than the identification of the peaks and that even higher resolving power, such as that developed for analysis of physiological fluids,[17] has a role in research on a new product.

An example of accelerated analysis [22] with 55 and 10 cm columns is given in Figure 7; the run time is about 5 hours. This particular chromatogram was obtained with Beckman AA-15 and AA-27 spherical resins at a load of 200 nanomoles. With range cards on the recorders, the Beckman 120-series analyzers give curves very similar to this one at 25 nanomoles.

The manufacturers of the many commercial instruments for this purpose have introduced their own important variations in the ion exchange resins, the ninhydrin reagent, and the automation, with further decreases in the run times.

The latest innovation (Figure 8) is a 70-minute analysis on a computer-operated instrument utilizing a 1.75 mm diameter column packed with 8 micron beads of resin and operated at a pressure of 2500 p.s.i. The instrument, involving a number of new principles of operation, has been designed by the Durrum Instrument Company, and draws upon the experience of Paul Hamilton[23] and of Edgar Hare[24] in the use of capillary columns. The narrower bore helps to make the analysis more micro; the curve in Figure 8 was obtained with 10 nanomoles of each amino acid. About 20 μg of protein are required for such an analysis. The precision at the 1-nanomole level is adequate for some purposes.

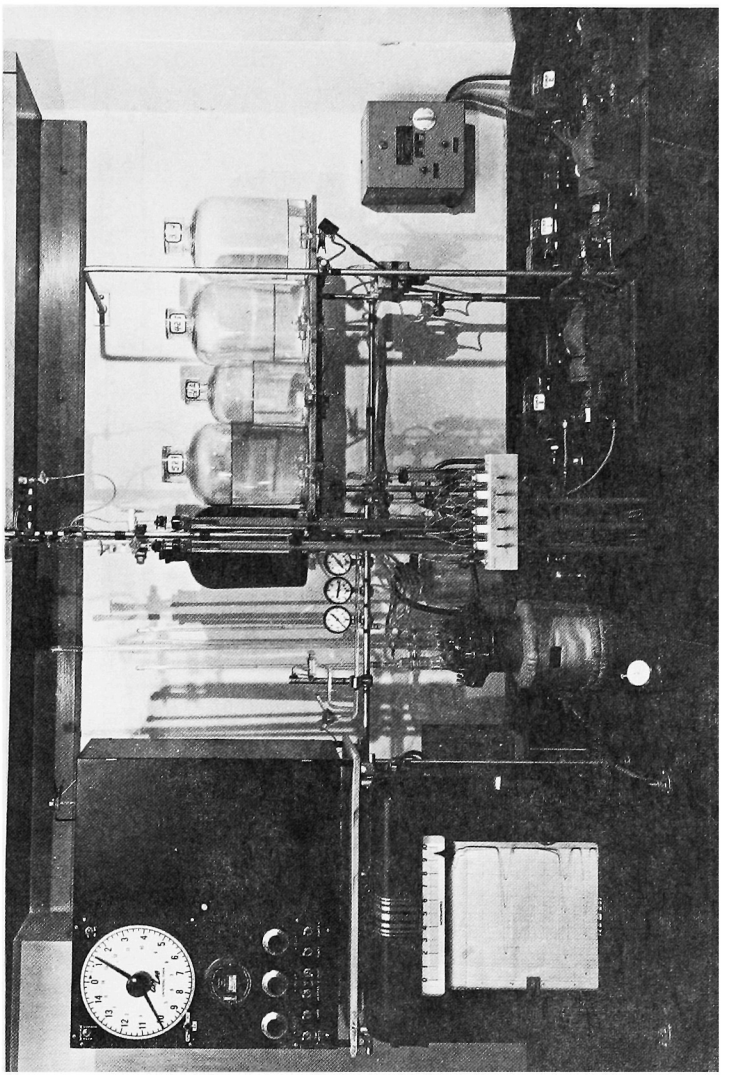

Figure 5: Automatic recording apparatus for the chromatography of amino acids (1958).[17]

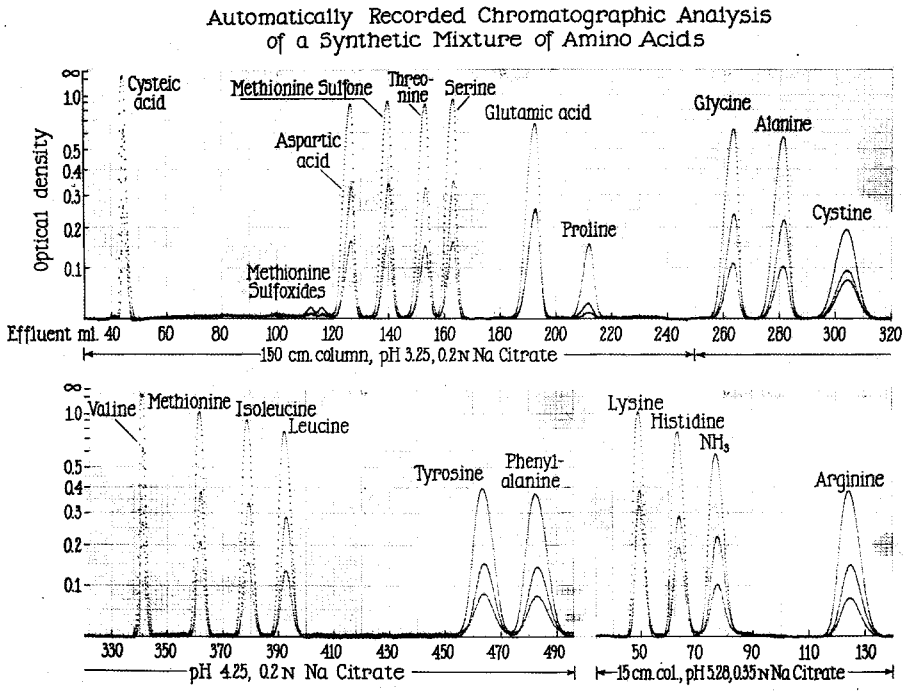

Figure 6: Chromatographic analysis of a mixture of amino acids automatically recorded in 22 hours (1958).[17] Load, 1 micromole per amino acid.

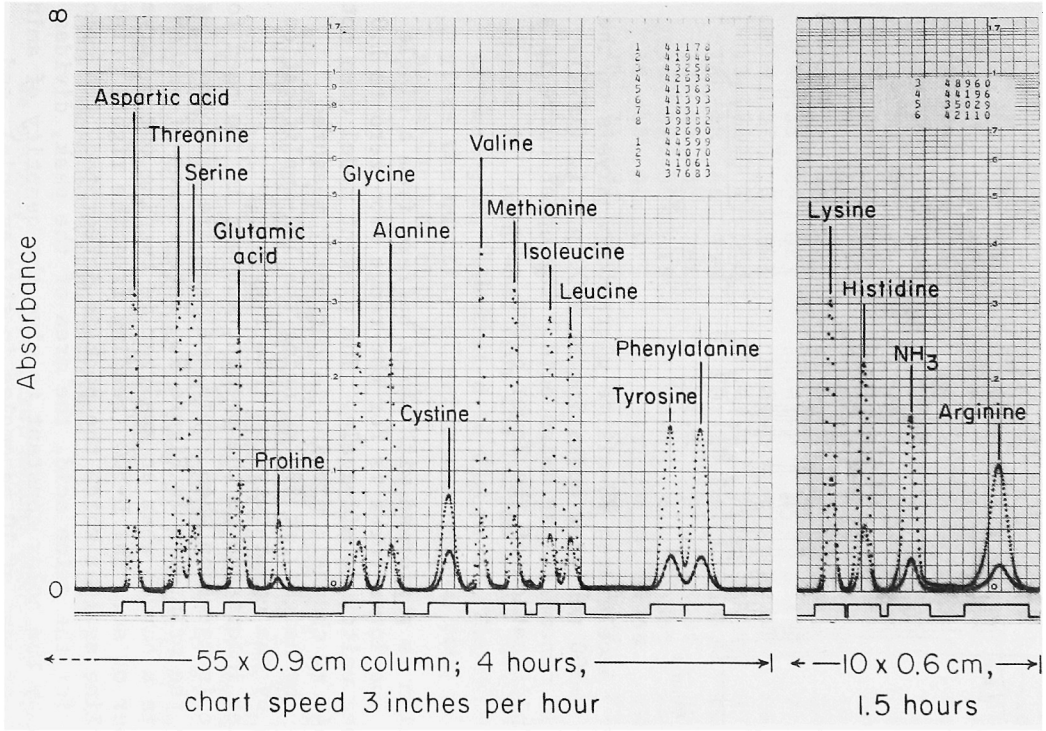

Figure 7: An accelerated 5.5 hour analysis (1963)[22] with 55 and 10 cm columns of Beckman AA-15 and AA-27 spherical resins operating at about 200 p.s.i. at 50 ml per hour. Load, 200 nanomoles per amino acid.

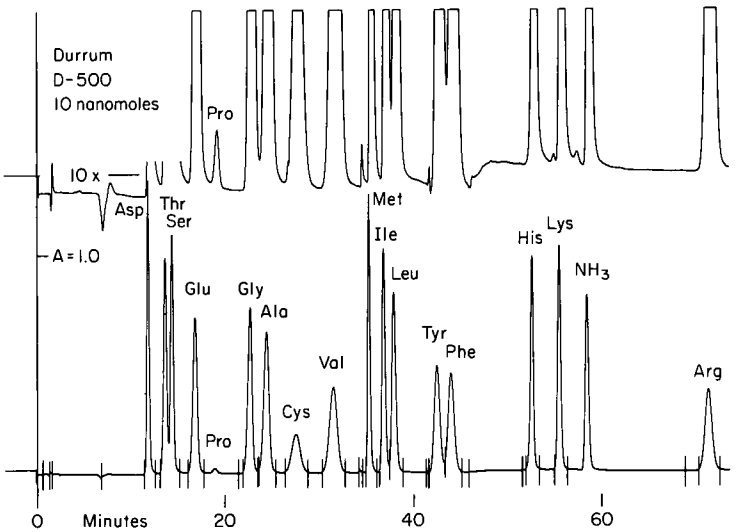

Figure 8: Accelerated 70-minute ultramicroanalysis on the Durrum D-500 analyzer operating at 2500 p.s.i. (1972). Load, 10 nanomoles per amino acid. The upper curve is a 10X amplification of the lower curve.

Elution is performed with three buffers from a single column. The lower curve is for the range from zero to 1.0 absorbance units, to mid-scale. The present model does not have a 440 mμ channel; proline is currently measured manually (by height) at 590 mμ using the 10X-amplification recorded by the upper curve on this figure.

Of key importance to the present subject is the need for automatic integration when rapid analyses are performed, as shown by the print-out in Figure 9. Integration of peaks by hand is a burden when an analyzer is turning out a curve every hour or so. The D-500 (reading from the right) prints the baseline against which the peak is integrated, the color constant for the amino acid, the area of the peak, divides the area by the color constant to give the quantity of amino acid (in per cent of 10 nanomoles in this example), and records the name of the amino acid and its elution time.

With automatic integrators that plot or print the baseline against which the peaks are read and mark the beginning

and end of each integration, it is possible to inspect the curve and make rapid graphical corrections if baseline shifts have not been fully accounted for. The use of a computer to handle the data from the spectrophotometer of an amino acid analyzer offers refinements in data handling that are being explored in several laboratories and by the manufacturers of such equipment.

The Precision of the Analyses

We showed,[14] in our first manual methods, that with the stable amino acids all of the amino acid that is placed on the top of the ion exchange column comes out in the peak at pH values below 7. The precision of the analysis depends upon the reproducibility of the photometric measurement, the

constancy of the flow rates in an on-stream analyzer, the sizes of the peaks, the steadiness of the baseline, the precision of the standard solution used for calibration, and the integration of the curves. With manual integration (height times width) and the original overnight run[17] in which resolution was optimum, the maximum deviation from theory was about 3% over a range going down to about 1/10th of full chart scale.

Spackman[25] has shown that this precision still holds with 5-hour accelerated systems but increases to a maximum deviation of about 5% for the 2-hour methodologies introduced in the 1960's. The analysis integrated in Figure 9, however, represents the result of an accelerated, high-pressure system that does not sacrifice resolution.

With any of these methods, if you run standards before or after the unknowns and average duplicate or triplicate analyses, the results can be closer to 100%, as Spackman[25] has shown in his discussion of the standard deviation of replicate runs.

Now let us turn to some actual results and to some of the problems of the hydrolysis step. Table I, obtained by Crestfield *et al.*[26] with the initial Spackman *et al.*[17] instrument, provides a practical example of some of the problems encountered in the analysis of a derivative of chromatographically purified natural ribonuclease A. With hydrolysis by 6 *N* HCl at 110° in evacuated tubes, it is usually rather precise to correct serine by 10% and threonine by 5% for the deamination occurring in 20-24 hours. For example, here, with reduced and carboxymethylated ribonuclease, in which the half-cystine residues are carboxymethylcysteine, if you add 10% to 13.6 you obtain exactly the theory of 15.0 residues for the relative molar amount of serine. If you add 5% to 9.48 you have the 10.0 residues of threonine. In principle it is of course sounder to determine the rate of destruction under the precise conditions of hydrolysis, as has been done here, by varying the hydrolysis time from 24, to 48, 73, and 102 hours and extrapolating to zero time. (For the stable amino acids, this table also gives an example of the reproducibility of replicate analyses.)

The small decrease in tyrosine with time, which occurred in this instance but is not always observed, can be insured against by including 0.2% phenol[27-29] in the 6 *N* HCl and the recovery of carboxymethylcysteine is made more certain by the inclusion of 0.1% mercaptoacetic acid. These precautions are especially important when peptides have been eluted from paper. Such additions can complicate the

†Extrapolated to zero time.

chromatogram, however, if cystine or cysteine is present. Cysteine is eluted at the proline position but can be air-oxidized to cystine after hydrolysis;[30] mercaptoacetic acid also causes small peaks under aspartic acid and near threonine.

The longer time of hydrolysis with HCl is needed with ribonuclease for another practical reason. The protein contains an isoleucyl-isoleucyl sequence[5] which is very slow to hydrolyze; 102 hours at 110° are required to give nearly three residues. Whenever isoleucyl-isoleucyl, valyl-valyl, or isoleucyl-valyl sequences are present this problem arises.

The precision of some of the other values in this table depends upon careful deaeration of the samples to below 50 microns before they are sealed under vacuum.[30] The largest deviation from theory in this table is for methionine which is 8% low, but that result is real; the chromatograms[26] showed traces of homoserine indicating a few per cent of alkylation of methionine by iodoacetate during the derivatization.

An alternative to the determination of half-cystine or cysteine as carboxymethylcysteine is to oxidize the peptide or protein with performic acid and measure cysteic acid;[31] methionine is simultaneously determined as the sulfone. The determination as S-sulfocysteine has also recently been studied.[32]

The analysis in Table I is calculated on the basis of molar ratios, taking alanine as 12 and arginine as 4. Usually the calculation of molar ratios is best based upon the average of the results for several of the stable amino acids (including glutamic acid, aspartic acid, alanine, and leucine). When a protein of unknown composition is being analyzed, the key calculation is the correlation of the molecular weight with integral numbers of those residues present in small molar proportions.

Purity on a weight basis can be fundamental in peptide chemistry, as Johannes Meienhofer and Yoshimoto Sano[33] have emphasized. If a weight recovery is desired, the protein or peptide needs to be carefully desalted, usually by gel filtration on Sephadex G-25 in 50% acetic acid. Samples of the lyophilized product are weighed for amino acid analysis and for moisture and residual ash determinations. For example, an analysis of streptococcal proteinase,[34] referred to a sample dried to constant weight in vacuo at 100° over P_2O_5, accounted for 98% of the weight and 99% of the nitrogen of the sample.

And a discussion of the relationship of amino acid analysis and purity would not be complete without including the caution emphasized by Klaus Hofmann and his associates[35]

that an amino acid analysis in agreement with theory is a necessary but not in itself a sufficient criterion for the purity of a synthetic peptide. Evidence for homogeneity by separation methods of adequate resolving power remains essential.

Most proteins contain tryptophan, which happens to be absent in ribonuclease, and which presents a special problem. It would be a great advantage to have a method of acid hydrolysis that would yield all of the amino acids, including tryptophan, which is labile under the usual conditions of hydrolysis in HCl. Hiroshi Matsubara and Richard Sasaki[36] found that the addition of 2 to 4% mercaptoacetic acid to 6 *N* HCl increased the recoveries of tryptophan to about 90% when carbohydrate was absent.

Teh-Yung Liu and Y. C. Chang[37] have recently made the important observation that when carbohydrate is absent, tryptophan undergoes only slight decomposition when 3 *N* *p*-toluenesulfonic acid is substituted for HCl and 0.2% tryptamine is included as a protectant. This method gave more than 90% recovery of tryptophan from ten proteins in 22 hours and multiple times of hydrolysis were used to obtain closer values by extrapolation to zero time. Teh-Yung Liu has subsequently found (Table II, personal communication) that he obtains even better results with

Table II

Hydrolysis of Proteins with 4 *N* Methanesulfonic Acid Containing 0.2% 3-(2-aminoethyl)indole at 115° for 24 hours From Teh-Yung Liu (personal communication; *cf.*[37]) (Theoretical integral residue numbers are given in parentheses)

Amino acid	*Lysozyme*	*Chymotrypsinogen*	*Myoglobin*	*Pepsinogen*
Tryptophan	5.95(6)	7.95(8)	1.90(2)	5.13(5)
Lysine	6.00(6)	14.00(14)	19.00(19)	11.00(11)
Histidine	1.05(1)	2.04(2)	11.68(12)	3.19(3)
Arginine	11.25(11)	3.91(4)	3.88(4)	4.12(4)

4 *N* methanesulfonic acid (1 ml containing tryptamine, subsequently neutralized with 1 ml of 3.5 *N* NaOH, and made to volume of 5 ml). At 115° he obtains 5.95 residues out of 6 in lysozyme, and similarly excellent results with chymotrypsinogen, myoglobin, and pepsinogen. He reports that by raising the temperature to 125° valine and isoleucine can be nearly completely liberated from their resistant linkages in 20 hours. It may well be that Teh-Yung Liu has arrived at the acid hydrolysis method of the future for carbohydrate-free peptides and proteins. One disadvantage is that the acid is not volatile and the neutralized hydrolysate ends up as a more dilute solution of amino acids than need be the case when HCl is used. When an ultramicro analyzer is employed, such as the Durrum D-500 instrument, which can take only a 40 µl sample, only a small percentage of the hydrolyzed peptide or protein can currently be utilized for amino acid analysis. This is only a problem when conservation of sample is critical. An important limitation of the procedure is that in the sulfonic acid solutions tryptophan remains sensitive to the presence of carbohydrate; when 5% or more of carbohydrate is present, the loss of tryptophan is appreciable.

The surest way to obtain complete recovery of tryptophan is to perform an alkaline hydrolysis specifically for that purpose. This year, Tony E. Hugli has succeeded in making alkaline hydrolysis by 4.2 *N* NaOH in the presence of carbohydrate a strictly quantitative procedure for tryptophan;[38] it is possible to obtain 100 ± 3% recoveries of the amino acid. The chromatography (Figure 10) is performed on an 8 cm column of Beckman PA-35 resin in 35 minutes with 0.21 *M* sodium citrate buffer at pH 5.28. This system, suggested by David Eaker, separates tryptophan from lysinoalanine which Zvi Bohak[39] showed can form during alkaline treatment of proteins. With the buffer usually employed on a short column at pH 5.28, these two amino acids overlap and high apparent values for tryptophan can result.

The results with nine proteins are shown in Table III. With sperm whale apomyoglobin, one of the tryptophan residues occurs in a valyl-tryptophan sequence and we encounter the usual problem of the slow hydrolysis of isoleucyl- or valyl-bonds. In this instance, 98 hours at 110° or 48 hours at 135° gave nearly the theoretical value for tryptophan.

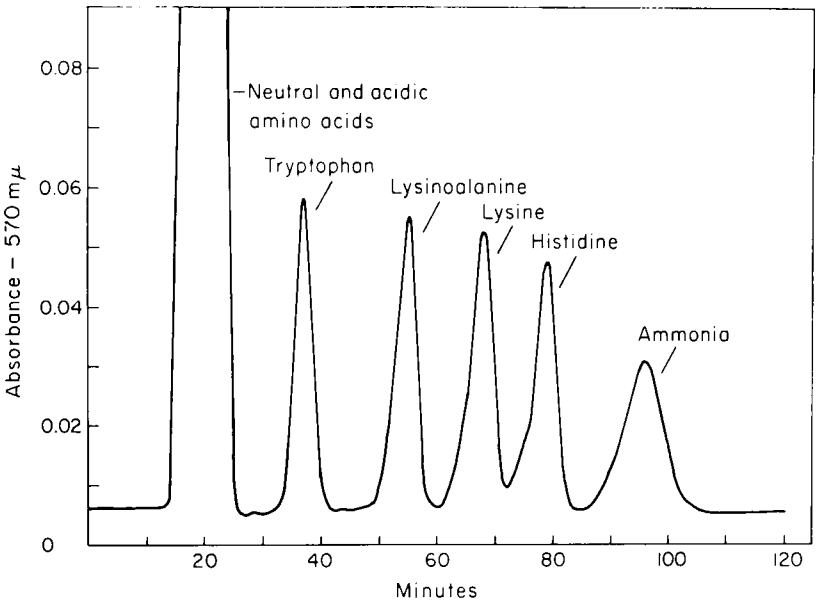

Figure 10: Chromatographic separation of tryptophan from other amino acids by ion exchange.[38] A 0.9 x 8.0 cm column of Beckman PA-35 resin was developed at a buffer flow rate of 50 ml per hour at 52° with 0.21 *M* sodium citrate buffer at pH 5.4. Ornithine, if present in an alkaline hydrolysate is eluted just ahead of lysine.

The details of the procedure which make possible the good recoveries by alkaline hydrolysis include the use of polypropylene liners in glass tubes, introduced by Mark Stahmann's laboratory[40] and the addition of starch[41] as the most effective antioxidant tested. Michael Draper at The Rockefeller University has been using this method to determine the tryptophan content of synthetic peptides with maximum precision. Spectrophotometric methods for tryptophan can be used on the intact peptide without the problem of hydrolysis if the peptide is soluble and the tyrosine: tryptophan ratio is not too high. But we admit to a preference for seeing a peak from chromatographically pure tryptophan on a chromatogram. Enzymatic hydrolysis is an

attractive alternative in principle, but as yet has not proved capable of giving complete hydrolysis in all instances; when successful for tryptophan, the chromatography is straightforward. (In another context, enzymatic hydrolysis is essential if chromatographic differentiation of glutamine and asparagine is to be made with the lithium buffer systems of Benson, Gordon, and Patterson[42]).

Analyses of Peptides

Let us consider now the precision of some analyses of peptides smaller than ribonuclease. In Table IV are the results of analyses of two thirteen-residue peptides isolated by gel filtration after cyanogen bromide cleavage of

Table IV

Amino Acid Compositions of Tridecapeptides Isolated After Cyanogen Bromide Cleavage of 3-Carboxyalkyl-His-12-RNases From Heinrikson *et al*[43]

ribonucleases alkylated at histidine-12.[43] The determination of homoserine and its lactone is not precise, because the two are in equilibrium during chromatography. But for the other amino acids the values for the number of residues check theory to within 3%. The analyses of well-purified peptides are usually reported to two decimal places. The approximate corrections of 10% and 5% have been applied to serine and threonine.

A single analysis of a 27-residue peptide isolated by ion exchange chromatography from a tryptic hydrolysate of streptococcal proteinase[44] is tabulated in Table V. The maximum deviation is 7% for valine; a closer value on valine would have required longer than 22 hours of hydrolysis. This peptide was deemed pure enough to merit sequence determination which was completed by Teh-Yung Liu and which fitted the analysis.

Table V

†Amino acids present to less than 0.01 residue omitted.

In sequence work we generally round off the analytical values to one decimal place because the degree of purification of the sub-fractions and the sequentially degraded products usually does not justify the second figure. But a synthetic peptide of this size would merit the expression of as much precision as the analysis can provide.

Without burdening you with more tables of this type, we hope that we have answered Ralph Hirschmann's original question concerning the precision with which an amino acid analysis by ion exchange chromatography can currently be expected to agree with theory under favorable conditions

with replicate runs or in a single rapid analysis such as this one.

D- and L-Amino Acids

So far, we have not used the letters D- and L-. The ion exchange columns do not differentiate between D- and L-isomers. James Manning, at the second symposium of this series in Cleveland, summarized the procedures through which the chromatography can be extended to the determination of the stereochemical purity of amino acid residues in synthetic peptides. We will use one chromatogram (Figure 11) to cross-refer to that report.[45] The method[46]

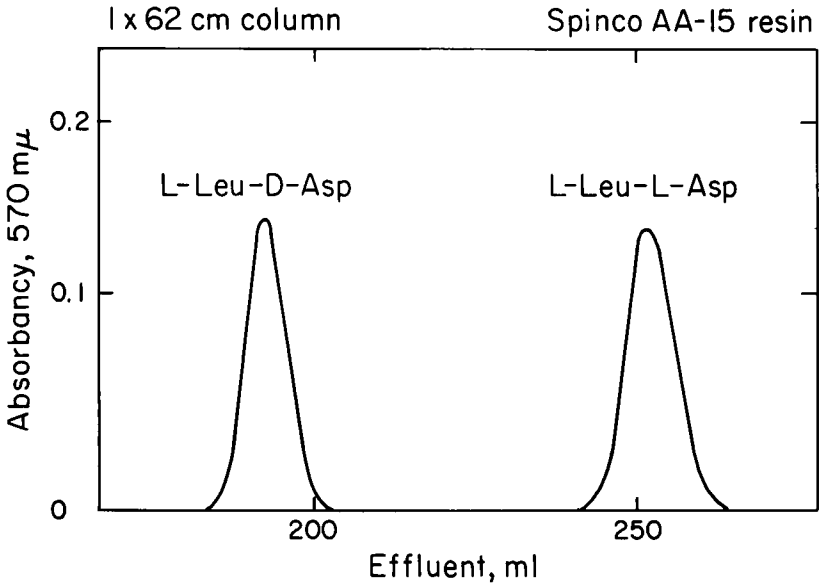

Figure 11: Separation of diastereoisomeric dipeptides on Beckman AA-15 resin (column 0.9 x 62 cm) at pH 3.25 and 52°.[46]

depends upon the conversion of the D- and L-isomers into diastereomers by condensation with L-leucine *N*-carboxyanhydride or L-glutamic acid NCA by the method of Hirschmann and associates.[47] The resulting pairs of dipeptides are separated on an amino acid analyzer. The resolution is such that by using high loads of the L-L dipeptide, the

stereochemical purity of the starting amino acids for peptide synthesis can be established to 99.99%. Robert Feinberg in Bruce Merrifield's laboratory has been giving this procedure an extensive work-out.

The determination of the stereochemical purity of an amino acid residue in a synthetic peptide is a more difficult problem. Some means of correcting for racemization during acid hydrolysis is needed. When the naturally occurring L-peptide is available, its hydrolysis provides a practical control. Bruce Merrifield suggested that when the natural peptide is not available, hydrolysis in tritiated HCl might provide the answer. James Manning[48] found that tritium incorporation, as measured with a scintillation flow cell in series with the analyzer, was applicable to the measurement of racemization during hydrolysis with 10 of the common amino acids. By a combination of the chromatographic experiments, the stereochemical purity of the residue in the parent peptide can be established with an accuracy of about 1%.

Discussion

We have limited this review to the precision of amino acid analysis by ion exchange chromatography. There are participants in this symposium who are experts on gas chromatography of amino acid derivatives and each advance in that technique is a welcome addition to the tools of protein chemistry. John Pisano[49] has written a very thoughtful summary of the subject for Vol. XXV of Methods in Enzymology. When derivatization is an integral part of the chemical procedure, as in the formation of thiohydantoins in the Edman degradation, the products are very logical candidates for gas chromatography. For the determination of amino acids, any derivatization process adds the variations in the yields of the derivatives to the errors inherent in the chromatographic process. Where precision is a major objective, there are advantages in avoiding the additional sources of error. The researches on rendering gas chromatography an efficient method for amino acid analysis have been stimulated by the potential speed, convenience, and sensitivity of the process. In the meantime, the progress in liquid chromatography has essentially matched gas chromatography in terms of speed and of sensitivity; the next contribution to this symposium, by Sidney Udenfriend, will be touching on the latter point. The main potential advantage of gas chromatography may then rest in

the simplicity of the separation process; any advance that makes amino acid analysis easier and cheaper will be quickly utilized.

Acknowledgments

The author is indebted to Ralph Hirschmann for suggesting the theme of this contribution, to Teh-Yung Liu for generously keeping us up-to-date on his experiments with methanesulfonic acid prior to publication, and to William H. Stein, James M. Manning, Tony E. Hugli, R. Bruce Merrifield, and Alexander R. Mitchell for reviewing this manuscript.

CHEMISTRY AND BIOLOGY OF PEPTIDES

A NEW FLUOROMETRIC PROCEDURE FOR ASSAY OF AMINO ACIDS, PEPTIDES AND PROTEINS IN THE PICOMOLE RANGE

Sidney Udenfriend, Stanley Stein, Peter Bohlen, Wallace Dairman. Roche Institute of Molecular Biology, Nutley, New Jersey.

SUMMARY--The application of a novel reagent, fluorescamine, to the assay of picomole quantities of primary amines is presented. Fluorescamine which is nonfluorescent, combines almost instantaneously with primary amines to yield highly fluorescent products. Excess fluorescamine is rapidly destroyed by water to yield nonfluorescent products. The reagent has been utilized in the development of an automated amino acid analyzer which can measure as little as 50 picomoles of each amino acid. The assay has also been successfully applied to the automatic monitoring of peptides from column effluents. A manual method and a semi-automated procedure have been developed for measuring proteins in the nanogram range. Fluorescamine has also been shown to be more sensitive than existing procedures for monitoring the extent of reaction in solid phase peptide synthesis.

PRIMARY AMINES COMPRISE a large number of biologically important substances and many procedures have been introduced over the years for their quantitative assay. More and more sensitive methods have been required as biological sophistication has increased. Our laboratory has previously reported that ninhydrin and phenylacetaldehyde combine with primary amines in a ternary reaction to form highly fluorescent products.[1] This reaction has been applied to the fluorometric assay of amino acids and peptides in the picomole range.[2] Subsequently Weigele *et al.*[3] investigated

the mechanism and determined the structure of the fluorophors obtained from several primary amines (Figure 1). This led

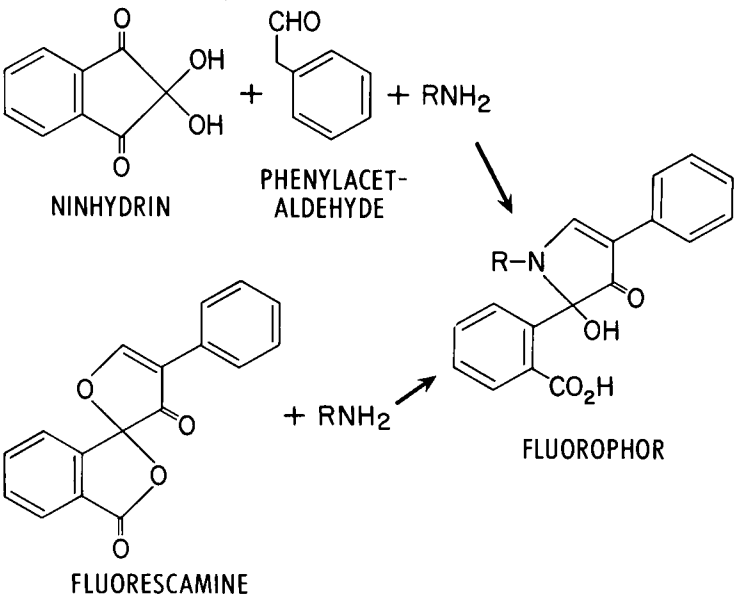

Figure 1: Reaction of primary amines with ninhydrin and phenylacetaldehyde and with fluorescamine.

Weigele *et al.*[4] to synthesize the reagent, 4-phenylspiro [furan-2(3*H*), 1'-phthalan]-3,3'-dione (fluorescamine) (Fluram)* which reacts with primary amines in a binary reaction to yield the same fluorophors as are obtained in the ternary reaction with ninhydrin and phenylacetaldehyde (Figure 1). The fluorophors in both reactions have excitation maxima at 390 nm and fluoresce maximally at 475 nm (uncorrected).

Fluorescamine has properties which offer many advantages that are unique among existing amine detecting reagents. The reagent itself is nonfluorescent. The fluorescamine

---

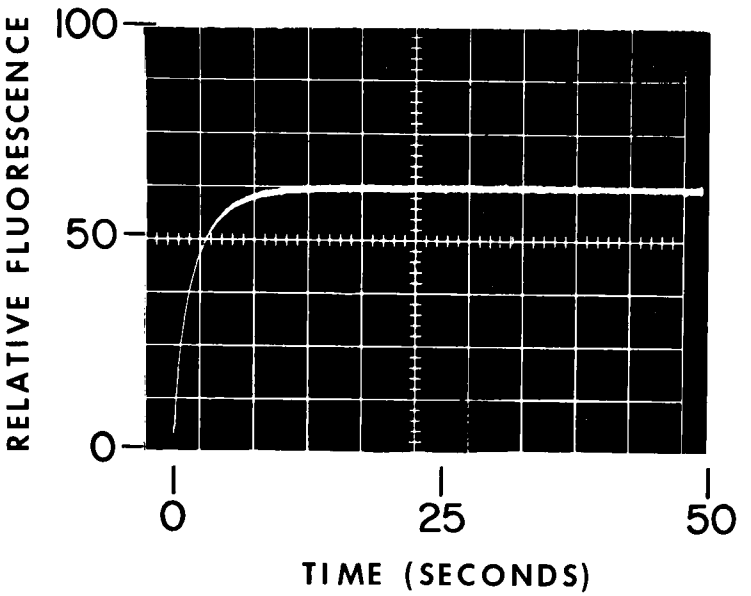

Figure 2: Oscilloscope photograph of the reaction of fluorescamine with alanine at pH 9.0 in the Aminco-Morrow stopped-flow fluorometer.

reaction with primary amines is extremely rapid at alkaline pH (Figure 2) and the fluorescent product is relatively stable. At pH 8-9 the average half-time for appearance of maximal fluorescence is measured in hundreds of millseconds at room temperature. Under the conditions of assay which are presently used there is a competing reaction of fluorescamine with water which leads to nonfluorescent degradation products. The latter reaction has a half-time of several seconds. The reaction has been shown to proceed almost to completion with a large number of amino acids and peptides (80-90% of the theoretical yield). In other words, one adds a nonfluorescent reagent to a solution containing an amino acid, peptide or protein and within a matter of seconds maximal fluorescence, which is quite stable, is obtained. Very shortly thereafter the excess reagent is destroyed by reaction with water to yield nonfluorescent products.

The advantages of fluorescamine are significant. The sensitivity is such that picomole quantities can be assayed

The rapidity of the reaction simplifies automation immensely, since there is essentially no delay and no heating apparatus is required. These properties are ideal for monitoring column effluents. In the short time since this reagent was introduced it has already found many applications.

Amino Acids

An automated apparatus has been developed for fluorometric amino acid assay. This is shown schematically in Figure 3. The column effluent mixes first with borate buffer to adjust the pH to 9, and then with fluorescamine in acetone. A coil of microtubing with a time delay of twenty seconds is sufficient to permit complete reaction and destruction of excess

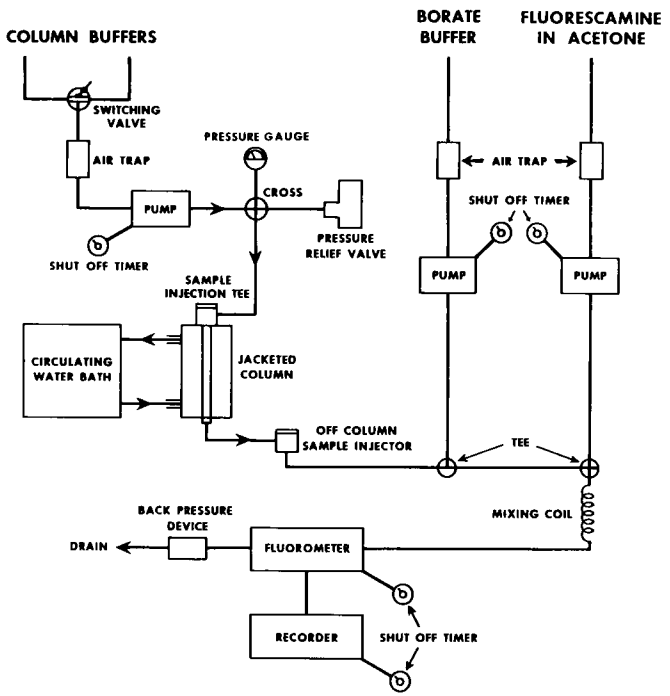

Figure 3: Schematic illustration of the flow system for automated assay with fluorescamine. Milton Roy minipumps were used for the column as well as for the 0.2 *M* sodium borate, pH 9.7 and 15 mg% solution of fluorescamine in acetone. A Beckman recorder and an Aminco filter fluorometer were employed.

reagent. Following this the solution passes through the flow cell of an Aminco microfluorometer. The signal is monitored on a strip chart recorder.

Chromatography of a mixture containing 250 picomoles each of neutral, acidic and basic amino acids is shown in Figure 4. Proline, which was present in the mixture, does

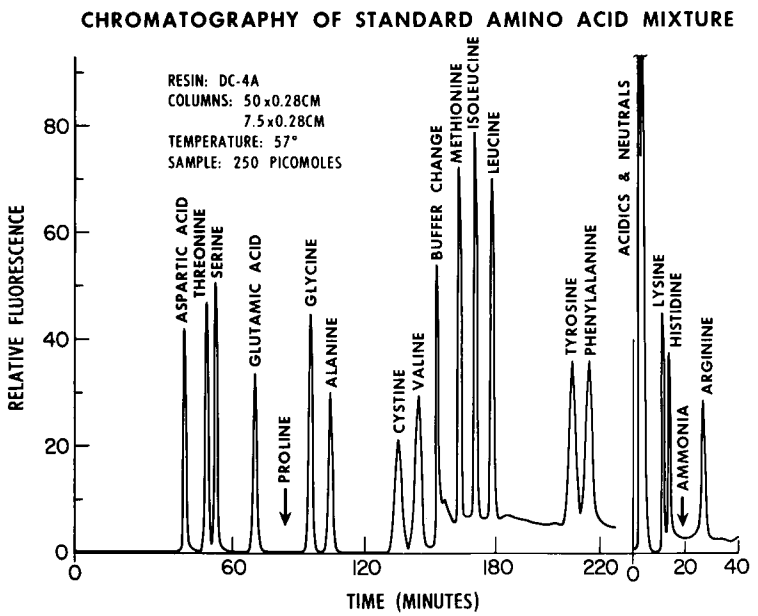

Figure 4: Chromatography of a standard mixture of 250 picomoles of each amino acid (including proline and ammonia) on a 50 x 0.28 cm acidics and neutrals column and a 7.5 x 0.28 cm basics column. Durrum DC-4A resin and Beckman concentrated citrate buffers were used. Flow rates were approximately 7 ml/hr for the long column and 12 ml/hr for the short column.

not appear because it is a secondary amine and therefore nonreactive. This is a disadvantage of the method which, it is hoped, will be overcome by additional research. A great advantage of fluorescamine is that the reaction with ammonia yields fluorescence which is only one-thousandth that obtained with amino acids. Ammonia, therefore, does

not interfere in the assay of basic amino acids. Neutral, acidic and basic amino acids can be assayed on this relatively simple apparatus to at least 50 picomoles. Proportionality of the fluorescence obtained with increasing amounts of arginine is shown in Figure 5.

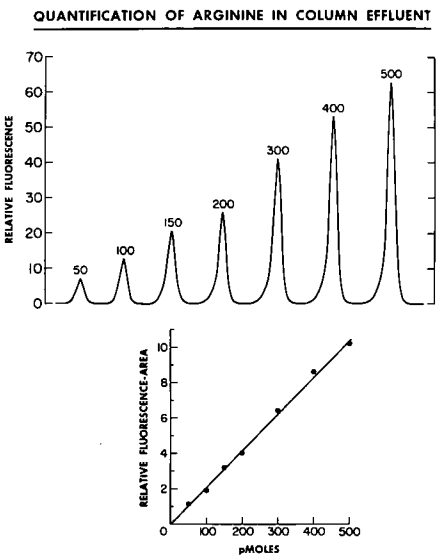

Figure 5: Linearity of fluorescence with quantity of arginine applied to the short column. The lower portion is the integrated area of each of the above recordings.

The procedure as described above has been applied to the assay of amino acids in microliter quantities of serum and urine. It has also been applied to the assay of microgram quantities of protein hydrolysates.

Peptides

The fluorescence obtained with peptides has been found to be greater than that obtained with amino acids. This appears to be due to an increased quantum yield of the resulting fluorophors. Dipeptides, pentapeptides, octapeptides and even insulin and glucagon give intense fluorescence permitting assay in the 20 to 100 picomole range. Of great interest is the effect of pH on fluorescence (Figure 6). The optimal range for amino acids is between pH 8 and 9.

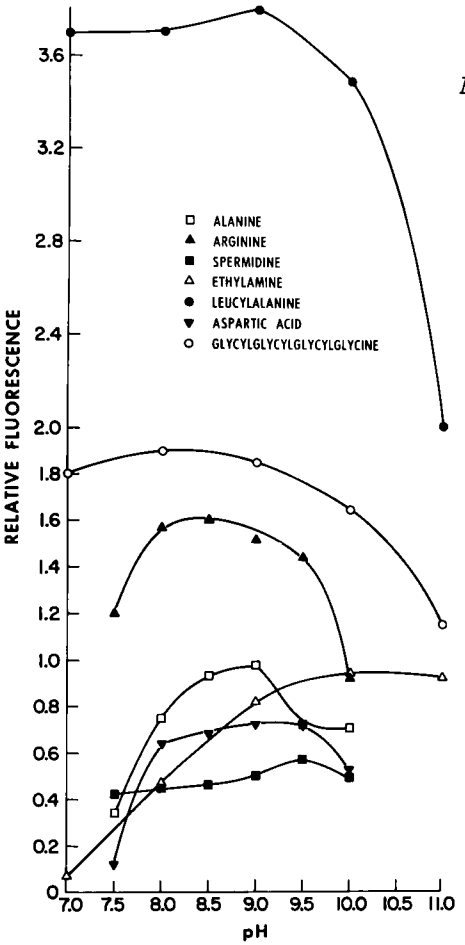

Figure 6: Influence of pH on the reaction of various primary amines with fluorescamine. One volume of fluorescamine in acetone was added to three volumes of the amine in sodium borate buffer.

However, when the pH is lowered, amino acid fluorescence falls off sharply. At pH 7 the fluorescence is less than a few percent of that obtained at pH 9. In contrast, at pH 7 peptide fluorescence is almost as high as at pH 9. This differential effect of pH should make it possible to use fluorescamine to detect peptides in complex mixtures without the need for fractionation.

Fluorescamine has been used to detect peptides in urine and tissue extracts and for following the metabolism *in*

vitro of vasoactive peptides in the picomole range. Studies on tryptic peptides of proteins for genetic comparison can be carried out with less than 100 micrograms of protein. Pituitary hormones have been assayed in extracts obtained from milligram amounts of tissue.[5]

Proteins

The amino groups of proteins react readily with fluorescamine to give intense fluorescence. Two types of procedure have been utilized for protein assay. The first is a manual method in which protein sample, buffer and reagent solution are mixed and fluorescence measured in a cuvette. Using the Aminco spectrophotofluorometer the method can measure as little as 0.5 μg per ml and the response is linear up to at least 100 μg per ml. To increase sensitivity a semi-automated procedure has been used. The automated apparatus shown in Figure 3 was modified to make use of a short column of Biogel. Each sample for assay is injected onto the Biogel column in order to separate proteins from small molecules which may also react with the reagent. The fluorescence in the protein peak is compared with standards (usually bovine serum albumin) passed over the same column. As a result of the small bed volume of the column and the rapid rate of reaction, each sample requires only a few minutes for assay. The continuous flow also gives a very stable baseline fluorescence which permits assay of as little as 50 nanograms of protein.

Fluorescamine has been applied to the measurement of protein in the determination of specific activities of fractions collected from column eluates during enzyme preparation. This has been done in a discontinuous manner. Continuous monitoring of very dilute solutions of protein in column effluents should also be possible.

Fluorescamine has also been applied to the detection of amino acids and peptides on thin layer and paper chromatograms. As little as 10 to 20 picomoles of peptides can be seen on thin layer plates.

A potentially useful application of the new reagent is for monitoring consecutive stages of solid-phase peptide synthesis. A major problem in this procedure is the failure of small amounts of the free amino group attached to the resin to react complete with the next protected amino acid. Even a fraction of a percent of unreacted amine at each step can result in the accumulation of a large amount of impurity in the desired peptide in a multi-step synthesis. Methods for monitoring completeness of reaction have been introduced.

They are usually time consuming and not sufficiently sensitive. A. M. Felix and J. Jimenez[6] have developed a method using fluorescamine for this purpose. From their results, it is evident that the new reagent can detect much smaller amounts of incomplete coupling with greater simplicity than has heretofore been possible.

Fluorescamine yields highly fluorescent products with other types of primary amines. Quantitative assays for catecholamines and polyamines[7] such as spermine and spermidine are being developed. The effects of various parameters such as temperature, pH, organic solvent and buffer salts on the reactivity and stability of fluorescamine are still under study. A thorough understanding of their influence should result in the best possible conditions for the use of fluorescamine and lead to many additional analytical applications.

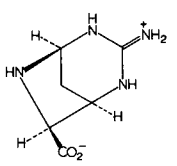
THE STRUCTURE AND CONFORMATION OF THE TUBERCULOSTATIC ANTIBIOTIC VIOMYCIN

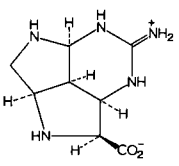
B. W. Bycroft. Department of Chemistry, University of Nottingham, Nottingham NG7 2RD, England

THE ANTIBIOTIC VIOMYCIN, first isolated[1] in 1951 from submerged cultures of certain species of *streptomyces*, has found limited clinical use in the treatment of tuberculosis. Although it possesses relatively high potency against tubercle bacilli, the marked toxic effects have prevented the widespread application of the antibiotic and its main therapeutic value lies in the treatment of cases involving drug-intolerance and bacterial resistance.

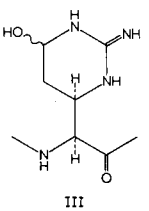
In view of the interest in the biogenesis of microbial peptide antibiotics and in structure-activity relationships in general, a knowledge of the chemical structure of viomycin was considered desirable. Initial investigations[2] had established the peptide nature of the antibiotic and shown that on acid hydrolysis it afforded the amino acids, L-serine, L-α,β-diaminopropionic acid, L-β-lysine and a new guanidine amino acid designated viomycidine (ratio 2:1:1:1 respectively) as well as urea and varying amounts of carbon dioxide and ammonia. Viomycidine, after some initial controversy, was assigned structure I[3] and this has recently been verified by several independent X-ray crystallographic analyses.[4]



I



II

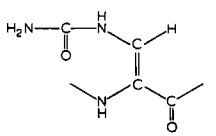


III

Our own investigations supported structure I for viomycidine but further degradative studies on viomycin, in particular mild base hydrolysis which yielded *inter alia* glycine and 2-aminopyrimidine in place of viomycidine, as well as an X-ray analysis of viocidic acid II, a minor product obtained on total acid hydrolysis, clearly demonstrated that viomycidine was not present as such in the intact antibiotic. This led us to suggest the presence of the structural unit III in viomycin for which it was possible to establish the absolute configuration at the α and β centers but not at the guanidine-carbinol center.[5] A number of transformations were interpreted on this basis, all of which paralleled closely those of the only other known naturally occurring guanidine-carbinol system which exists in the molecule of the fish poison tetrodotoxin.[6]

A further complicating feature of the chemistry of viomycin is the presence of an extremely labile chromophoric unit which is characterized by a strong ultraviolet absorption at 268nm (ε, 24,000) in neutral and acidic media, shifting to 285nm (ε, 15,000) in base. The lability of both the chromophore and the guanidine-carbinol units have presented considerable difficulties in interpreting degradative results and earlier formulations of the chromophore attempted to combine both these units whereas recent publications have misinterpreted results relating to the guanidine unit and took no account of the chromophore.

It was possible by kinetic studies to demonstrate that the urea was part of the chromophoric system and further extensive chemical and spectral studies led us to the formulation IV for the chromophore.[7] This was later substantiated by the synthesis of model systems which possessed similar chemical and spectral properties.[8]



IV

With the structures of the guanidine and chromophoric unit established it was possible, on the basis of end group analysis and the structures of dipeptides obtained from partial base hydrolysis, to propose tentatively the molecular structure shown in Figure 1 for viomycin.[9]

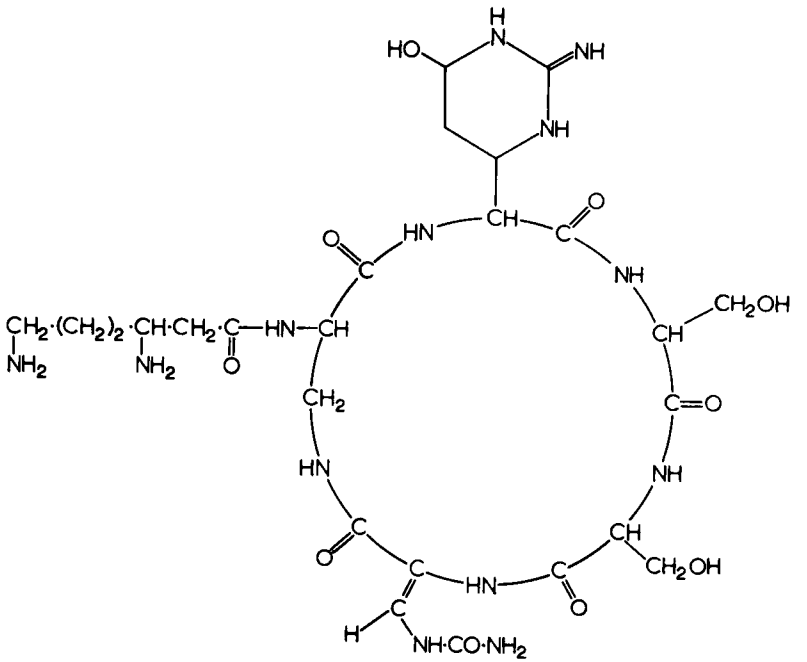


Figure 1: Structure proposed on the basis of chemical evidence

In order to substantiate this proposal the suitability of a number of derivatives of viomycin for X-ray crystallographic examination was investigated. Crystals of viomycin dihydrobromide hydrochloride $C_{25}H_{43}N_{13}O_{10}$. $2HBr \cdot HCl \cdot 3H_2O$, monoclinic, space group C_2 with cell dimensions a = 20.70(3), b = 15.79(3), c - 13.93(3), β = 106.17°, were subsequently prepared and the intensities of 1525 independent reflexions were recorded. Initial co-ordinates for the two bromide and chloride anions were obtained from a three dimensional Patterson synthesis and several successive rounds of structure factor calculations and Fourier syntheses phased on these ions revealed the molecular structure shown in Figure 2. The structure confirms the presence of the novel dehydroserine ureide IV and the guanidine-carbinol system III but necessitates an amendment to the proposed amino-acid sequence. It is of interest to note that the physical and spectral properties as well as the end group analysis of viomycin are in accord with both structures. The discrepancy arose over a misinterpretation of the origin of the dipeptides

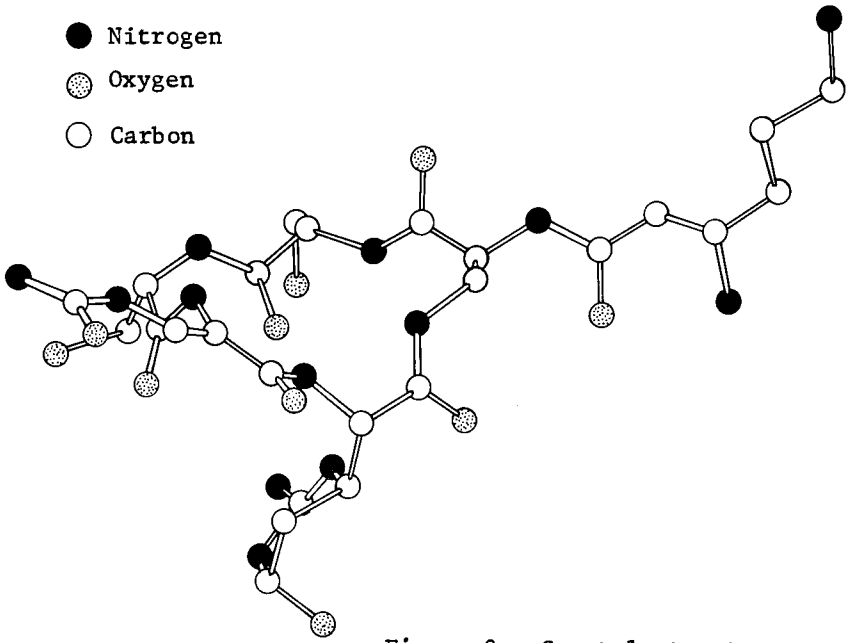

Figure 2: Crystal structure

obtained on base hydrolysis and serves to emphasize the caution that is necessary when determining the amino acid sequence of peptides containing labile amino acid units.

Since the L-configuration of the α-amino acids had already been determined the absolute configuration of the whole molecule is also established. A significant feature of viomycin in the crystalline state is the hydrogen bonded chelate ring Figure 3 the conformation of which is similar to the β-turn structure common to many other cyclic peptides.[10] The corner positions of the β-turn in cyclic peptides are normally occupied by the α-carbon atoms of a D- and L-amino acid residue respectively. Conformational energy considerations accord with the established stability of this type of system and there is abundant evidence to suggest that the β-turn conformation is retained in solution.[11] Initial 100 and 220 mHz NMR studies which are as yet incomplete provide evidence that this is also true for viomycin.

In viomycin these corner positions are occupied by L-serine and the dehydroserine ureide which replaces the usual D-amino acid residue. The presence of the same β-turn structure in the closely related antiobiotic

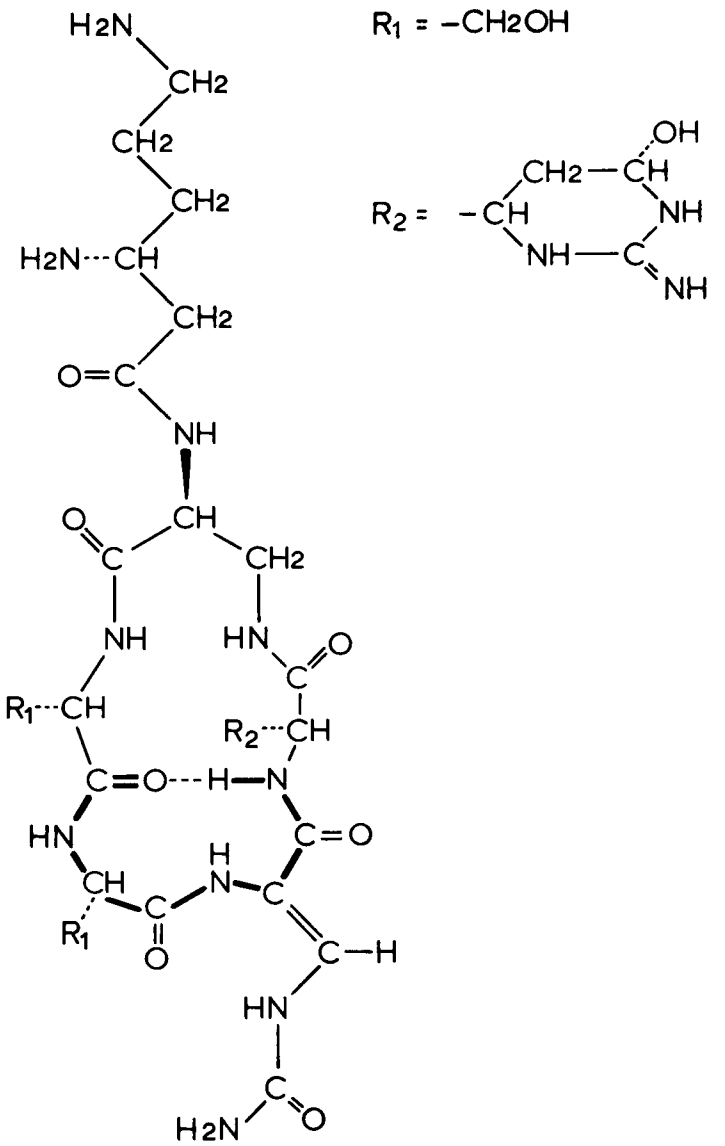

Figure 3: Correct structure showing the transannular hydrogen bond

tuberactinomycin has also been established by an X-ray crystallographic analysis.[12] This interesting conformational feature may be relevant to our views[13] concerning the possible relationship of D-amino acids and dehydroamino acids in microbial peptide antibiotics, as well as to the mode of action of this novel antibiotic.

CHEMISTRY AND BIOLOGY OF PEPTIDES

STRUCTURAL RELATIONSHIPS IN AND BETWEEN PEPTIDES WITH α,β-UNSATURATED AMINO ACIDS

Erhard Gross. Section on Molecular Structure, Laboratory of Biomedical Sciences, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland 20014

SUMMARY--Intramolecular structural relationships exist most obviously in peptide molecules with α,β-unsaturated amino acids and lanthionines. The most extensively studied structural relationships between molecules with α,β-unsaturated amino acids extend to nisin and subtilin, peptides from rather different microbial origins.

THE NATURAL OCCURRENCE of the α,β-unsaturated analogs of common amino acids has been demonstrated in at least ten cases.[1] Thus far, most α,β-unsaturated amino acids have been found in peptides of relatively low molecular weight of microbial origin.

Peptides with α,β-unsaturated amino acids may be divided into two classes: (a) those which contain a single α,β-unsaturated amino acid having no obvious structural relationship with other amino acids in the molecule; and (b) those peptides which contain one or more α,β-unsaturated amino acids that are structurally related with other amino acids present in the molecule.

To mention but one member of the first group, telomycin comes to mind. This peptide contains dehydrotryptophan, which was one of the first α,β-unsaturated amino acids found to occur naturally.[2]

A representative of the second group of peptides is nisin[3] (Figure 1). It contains three α,β-unsaturated amino

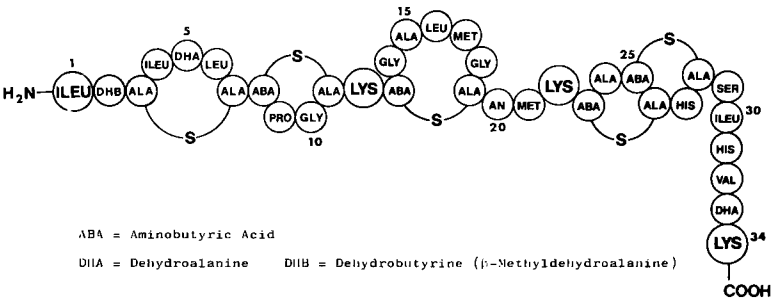

Figure 1: The structure of nisin.

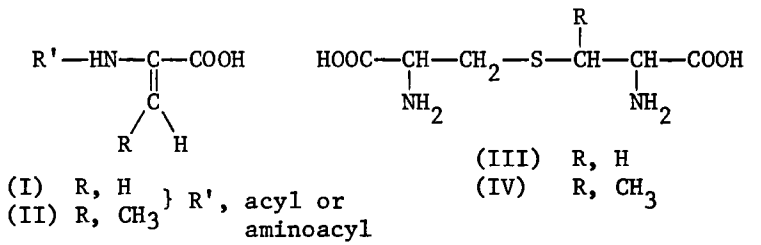
acids, namely, two residues of dehydroalanine (I) and one residue of dehydrobutyrine (β-methyldehydroalanine, II). There are also present in the molecule on residue of lanthionine (III) and four residues of β-methyllanthionine (IV).



(I) R, H
(II) R, CH_3
} R', acyl or aminoacyl

(III) R, H
(IV) R, CH_3

It is conceivable that the lanthionine and β-methyl-lanthionine residues are derived biosynthetically by the addition of cysteine to precursors in the form of the corresponding α,β-unsaturated amino acids (Figure 2). The potential of reversing the reaction via β-elimination and regeneration of the α,β-unsaturated amino acid (Figure 2) is evident.

Intramolecularly seen, another reversible reaction must be taken into consideration, namely the conversion of an α,β-unsaturated amino acid to amide and keto acid (Figure 3). In its reversible form, the reaction constitutes a peptide bond forming step which may well be operative in nature.

In addition to these relationships *within* a peptide containing α,β-unsaturated amino acids and residues of

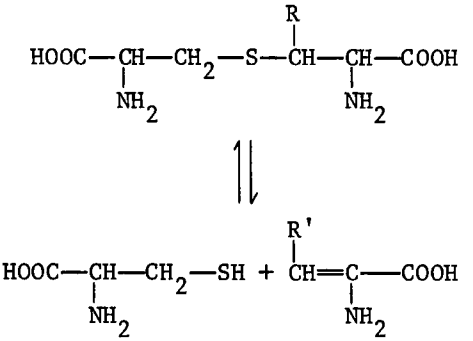


Figure 2: The structural relationship between the thioether amino acids lanthionine (R,H) and β-methyllanthionine (R,CH_3) and the α,β-unsaturated amino acids dehydroalanine (R',H) and dehydrobutyrine (=β-methyldehydroalanine, R', CH_3).

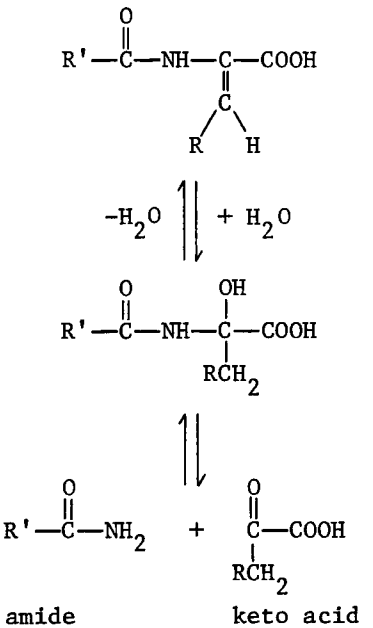

Figure 3: The reversible conversion of α,β-unsaturated amino acids to amide and keto acid.

lanthionine or substituted lanthionines, there are also structural similarities *among* representatives of these types of peptides from different microbial sources.

Structural relationships of this category are presently best established for nisin (from *Streptococcus lactis*) and subtilin (from *Bacillus subtilis*). Both peptides contain not only equal numbers of residues of dehydroalanine (two each), dehydrobutyrine (one each), lanthionine (one each), and β-methyllanthionine (four each), but also identical COOH-terminal sequences of dehydroalanyl-lysine[4] (*cf.* Figure 4). Furthermore, one finds repeated within the COOH-terminal region of subtilin (Figure 4) the unique thirteen-membered bicyclic heterodetic structure seen in nisin.[5]

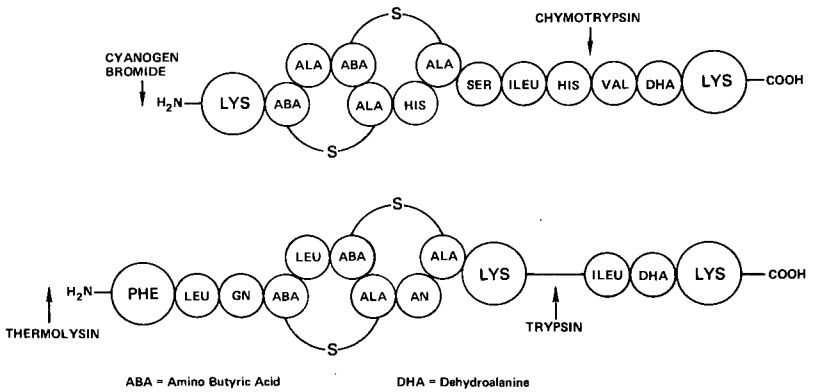

Figure 4: Analogous heterodetic bicyclic structures in the COOH-terminal fragments of nisin (top) and of subtilin (bottom).

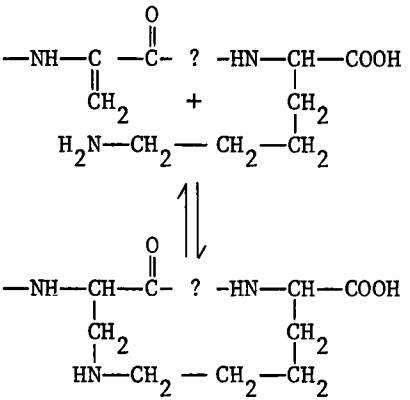
The extension of these studies to the lanthionine and β-methyllanthionine containing peptides cinnamycin[6] (from *Streptomyces cinnamoneus*) and duramycin[7] (from *Streptomyces cinnamoneus* forma *azacoluta*), to date, has furnished this information: these two peptides do no longer contain α,β-unsaturated amino acids. There is, however, unequivocal evidence that this structural element was once present in these molecules. In the form in which these peptides are isolated the α,β-unsaturated amino acids are masked by the addition of functional groups across the α,β-double bond. In cinnamycin and duramycin, the addition of the ε-amino group of lysine to dehydroalanine (Figure 5) formed



?: alanyllysine peptide bond or insertion of one or several amino acids

Figure 5: The addition of the ε-amino group of lysine to dehydroalanine.

lysinoalanine, the amino acid previously found in alkali-treated bovine pancreatic ribonuclease.[8]

It shall be interesting to establish the configuration of the α-carbon atom of the alanine moiety of lysinoalanine. The α-carbon atoms of the α-aminobutyric acid moiety in the β-methyllanthionine residues and in one of the alanine moieties of the lanthionine residue in nisin are all of the D-configuration. During the biosynthesis of these amino acids--so the hypothesis proposes--cysteine is added across the double bond of the corresponding α,β-unsaturated amino acid. In the absence of sequence data, the question remains open, whether there are amino acids inserted in lysinoalanine between the alanine and lysine moieties.

The *in vitro* formation of lysinoalanine from dehydroalanine and lysine was demonstrated by exposing the COOH-terminal fragment of nisin to an *N*-morpholine buffer of pH 11.4 for one hour at room temperature. Under these conditions lysinoalanine was formed rather readily (Figure 6).

The presence of α,β-unsaturated amino acids is not restricted to peptides of low molecular weight, nor to those of microbial origin. Dehydroalanine, for instance, has been identified in histidine ammonia lyase of both bacterial[9,10] and mammalian origin[11] and in phenylalanine ammonia lyase from a plant source.[12]

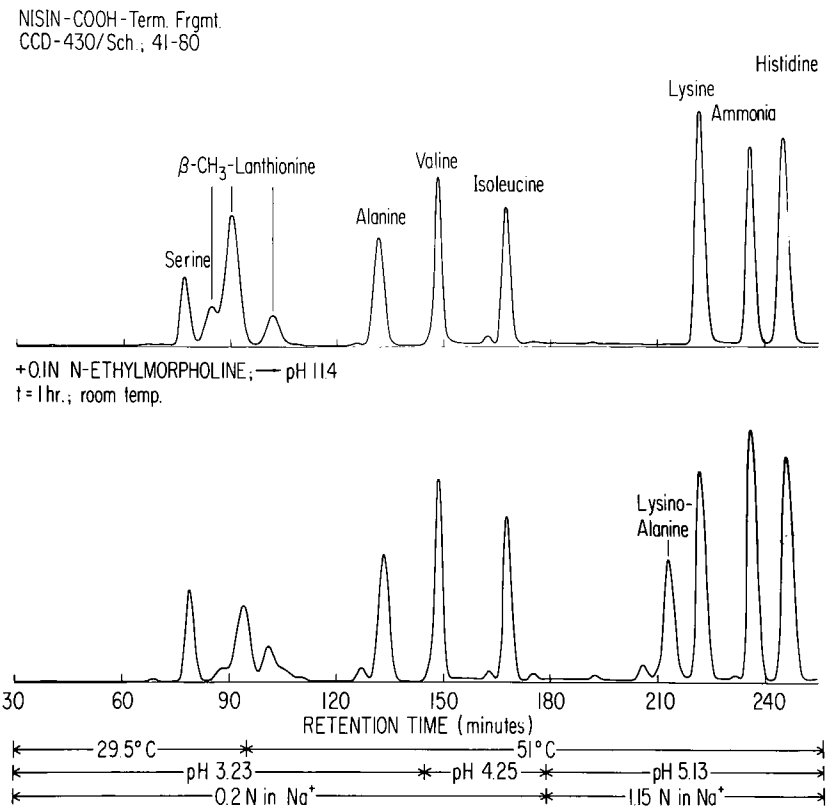


Figure 6: **Lysinoalanine formation in the COOH-terminal fragment of nisin under alkaline conditions.**

α,β-Unsaturated amino acids are likely to play a more important role in nature than is presently assumed. Frequently they may function in a rather cryptic way and escape detection on the grounds of their dynamic property of converting to other chemical entities (*cf.* Figures 2, 3, and 5).

The working hypothesis of such intermediary involvement of dehydroalanine was recently tested in part for the releasing factor of luteinizing and follicle stimulating hormone. Appropriate substitution of the serine residue in the releasing factor (Figure 7) should, via β-elimination and dehydroalanine formation, lead to the fragmentation of the decapeptide and result in the formation of the tripeptide amide and pyruvylhexapeptide amide.

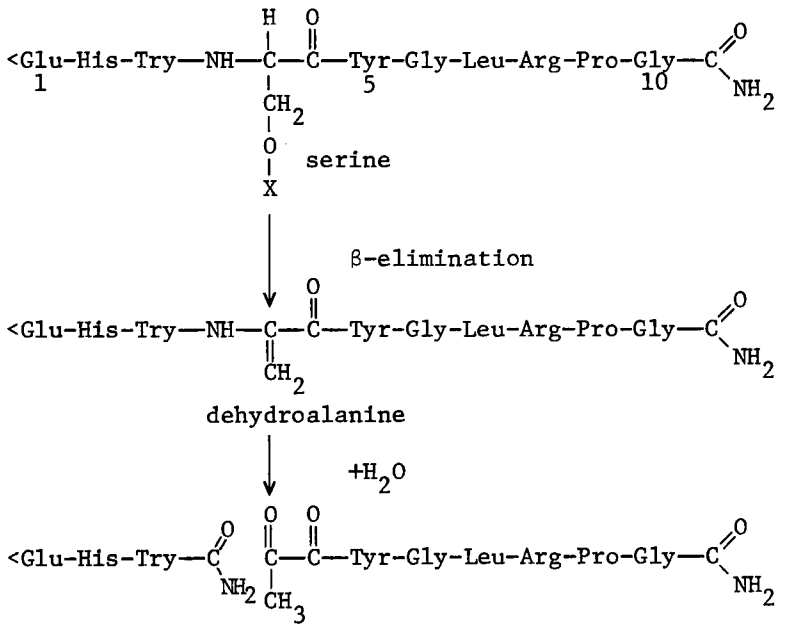

Figure 7: Fragmentation via β-elimination of the releasing factor for luteinizing hormone and follicle stimulating hormone.

At this stage of the investigation, the tripeptide amide has been provided by solid-phase peptide synthesis and been found to possess luteinizing hormone releasing activity and only this activity.[13]

Acknowledgment:

The able and enthusiastic collaboration of many co-workers is gratefully recorded. Mr. John L. Morell made possible the structural elucidation of nisin. Dr. H. H. Kiltz contributed much to the understanding of subtilin. Dr. Kiltz began the studies on cinnamycin which, since then, have been continued by Mr. Charles Chapin.

CHEMISTRY AND BIOLOGY OF PEPTIDES

A NEW TECHNIQUE FOR THE SEQUENCE DETERMINATION OF PROTEINS AND PEPTIDES BY GAS CHROMATOGRAPHY-MASS SPECTROMETRY-COMPUTER ANALYSIS OF COMPLEX HYDROLYSIS MIXTURES

H.-J. Förster, J. A. Kelley, H. Nau, K. Biemann.*
Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

OVER THE PAST DOZEN YEARS considerable efforts have been devoted to the development of new and efficient instrumental techniques for the amino acid sequencing of peptides and proteins.[1] Mass spectrometry offered great promise because of its high sensitivity and structural specficity for linear molecules. These mass spectral approaches centered around the interpretability of mass spectra of peptide derivatives but neglected the real problem in protein sequencing--working with very complex mixtures of degradation peptides on a submicromolar level. Recently, we have developed a technique which addresses itself to this problem, and the results obtained will be discussed below.

For various other investigations we had already developed a sophisticated gas chromatograph-mass spectrometer-computer (GC-MS-Computer) system. A crucial aspect of this approach is the generation of a mixture of small peptides that represents an as complete as possible record of all the peptide bonds present in the protein or primary degradation peptide. The identification technique must be able to handle all peptides (with one single reaction sequence) regardless of the nature of the amino acids present. Thus the main emphasis is to be placed on a high degree of completeness of identification of small peptides rather than

*Present Address: Gerichtlich-medizinisches Institut der Universität Zürich, Postfach 8028, Zürich, Switzerland.

the desire to handle as large a degradation peptide as possible, a process which is often limited by the presence of certain amino acids. At the outset we aimed at unambiguous identification of all possible di- and tripeptides in complex mixtures, but it turned out that the system can handle most tetra- and some pentapeptides as well; this substantially improves the confidence in the reassembly of the original structure.

Reduction of peptide derivatives produces polyamino alcohols which are well suited to both gas chromatographic separation and mass spectrometric sequencing.[2,3] Earlier difficulties with polyfunctional amino acids have now been overcome by *O*-trimethylsilylation of the polyamino alcohols and the efficient manipulation of peptide mixtures on a very small scale. A major effort was devoted to the generation of these peptide mixtures. Because of the diversity of the characteristics of proteins, one could not expect to find one mode of degradation applicable to all. Three different approaches were developed: (1) partial acid hydrolysis; (2) enzymatic cleavage utilizing a single enzyme or a set of enzymes; and (3) dipeptidylaminopeptidase I (cathepsin C) digestion before and after one Edman degradation step. The differences in specificity of these three govern the choice based on the amino acid composition and genesis of the original protein or peptide. Another major aspect of the problem required the development of interpretative techniques that could deal with the vast amount of data generated while analyzing an entire peptide mixture. These computer-assisted techniques are outlined later.

Extensive enzymatic and partial acid hydrolysis studies have been conducted on ribonuclease S-peptide to determine the feasibility of generating mixtures of overlapping oligopeptides which will allow reconstruction of the original peptide sequence. Mixtures have been generated by partial acid hydrolysis with 6 *N* HCl for 15 min to 16 hr and by employing enzymes such as chymotrypsin, papain, pepsin, pronase, subtilisin, trypsin-pepsin and trypsin-chymotrypsin. In a typical experiment 3.0 mg (1.37 μmol) of S-peptide was hydrolyzed. The hydrolyzate mixture was esterified, acetylated and reduced with $LiAlD_4$* to yield the corresponding polyamino alcohols. Silylation with pyridine-trimethylsilyldiethylamine (2:1) yields a corresponding mixture of *O*-silyl ethers that possess excellent gas chromatographic separability and produce easily interpretable mass spectra.

---

*$LiAlD_4$ is preferred over $LiAlH_4$ because it minimizes the occurrence of different sequence ions of the same mass.

The peptide derivative mixtures were analyzed by a GC-MS-Computer system that consisted of a Perkin-Elmer 990 gas chromatograph - Hitachi RMU 6L mass spectrometer combination operated on line with an IBM 1800 computer for data acquisition and control. The GC effluent is continuously scanned every 4 seconds through the mass ranges of *m/e* 28-455 or *m/e* 28-743. At the termination of the GC-MS experiment a total ionization plot, *i.e.* a computer-generated gas chromatogram obtained by summing ion intensities over the whole experiment (Figure 1a), mass spectra for every scan, and mass chromatograms (plots of the abundance of each mass during the gas chromatogram, such as Figures 1b and 1c) are generated. These are stored on magnetic tape for future data manipulation, and made available to the user as microfilm copies filmed from an oscilloscope display.[4] Thus the data is available for manual interpretation by inspection of individual mass spectra and analysis of selected GC peaks by mass chromatograms or for partially automatic interpretation by computer-assisted data manipulation[5] and automatic identification and sequence assembly programs.[6] Alternatively, a technique of controlled fractional vaporization of the sample directly into the ion source of the mass spectrometer using the same programs as GC-MS is available for identification of large peptides which are not amenable to gas chromatography.

The silylated polyamino alcohols possess a repetitive ethylenediamine backbone with carbon-carbon bonds which cleave upon electron impact to yield ions stabilized by neighboring nitrogen atoms and to produce mass spectra composed almost entirely of sequence indicating ions (Figure 2). Retention of charge on carbon atoms towards the N-terminal end gives rise to ions representing the sequence from the N-terminal side of the molecule (A_1, A_2, A_3 ...), while retention of charge at the other carbon atoms generates ions corresponding to the sequence from the C-terminal end of the molecule (Z_1, Z_2, Z_3 ...). A consequence of silylation is the presence of a fairly abundant M-15 ion, (loss of methyl from the molecule) which indicates indirectly the molecular weight. Inspection of the mass chromatograms corresponding to the *m/e* values of possible sequence determining ions enables one to rapidly identify the peptide derivatives. The importance of this technique for the identification of components of very complex mixtures cannot be overemphasized since it allows location of amino acid and peptide derivatives containing the same N-terminal amino acid. For example, a plot of *m/e* 150 (A_1 of Phe) as shown in Figure 1b locates

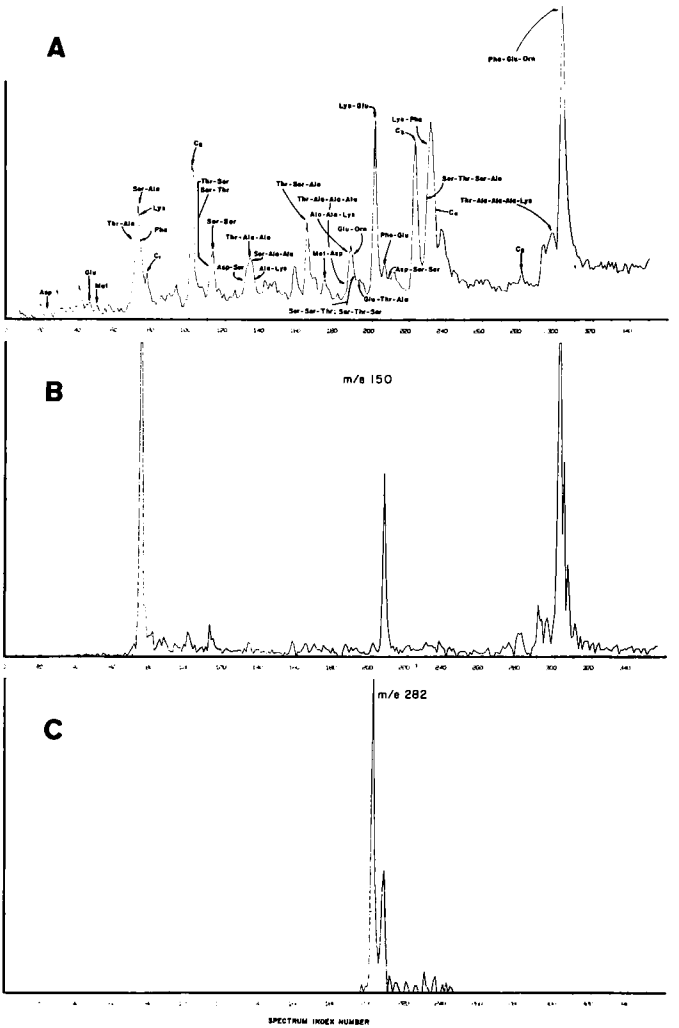

Figure 1: (a) Total ionization plot of silylated amino alcohols obtained by digestion of ribonuclease S-peptide by trypsin and pepsin followed by hydrazinolysis and subsequent derivatization. Figure 2: Mass spectrum of the silylated polyamino alcohol corresponding to Asp-Ser-Ser-Thr.

Phe, Phe-Glu and Phe-Glu-Orn. Similarly, peptide derivatives with a certain C-terminal amino acid are located by inspection of the corresponding mass chromatogram (*e.g. m/e* for the Z_1 of Glu, Figure 1c). The coincidence of maxima in mass chromatograms[7] of sequence ions makes it possible to locate and identify any peptide derivative in the gas chromatogram. For example, Phe-Glu, a relatively minor component of the mixture resulting from trypsin-pepsin degradation of S-peptide, can be readily located in the total ionization plot by mass chromatograms of *m/e* 150 and 282 (see Figures 1a-c at spectrum index number 208). Mass chromatograms also allow facile location of peptide derivatives in the presence of the unavoidable non-peptide artifacts (C_1-C_4 in Figure 1a) and the further resolution of incompletely separated components. As a further parameter the gas chromatographic characteristics, expressed by retention indices,[8] are used to great advantage. They can be calculated from values that are determined experimentally for each amino acid side chain. Since the reconstruction of the peptide structure from the sequence determining ions is a matter of simple arithmetic and the data is already residing in the computer, automation of interpretation and eventual assembly of identified overlapping peptides into the complete protein structure is possible. Several interpretive programs already exist for routine use.[6]

Table I shows the peptide derivatives that were identified by GC-MS and fractional vaporization experiments in the derivatized peptide hydrolyzate produced by trypsin and

pepsin digestion of S-peptide (hydrazinolysis is employed to transform arginine to ornithine).[10] All original peptide bonds are represented in these fragments except those involving glutamine. Consideration of the results of one such experiment permit a proper choice of the cleavage method which would complete the overlap, if necessary. Indeed, partial acid hydrolysis of S-peptide produces (after hydrazine treatment) Orn-Glu and Glu-His-Met, among others.

A promising third alternative is the use of cathepsin C which sequentially cleaves dipeptides from the N-terminal end of a peptide, except those with *N*-terminal Arg or Lys, and until it encounters Pro.[11,12] This enzyme would appear to be ideal for tryptic peptides where two cathepsin digests, one on the intact peptide and one on the Edman-degraded peptide, produce two sets of overlapping dipeptides. Identification of all the dipeptides then allows complete or partial reconstruction of the original sequence. This strategy, which was recently also explored by others,[13-15] was tested on glucagon and several tryptic peptides from rabbit skeletal muscle actin.* GC-MS-Computer analysis of silylated oligopeptide amino alcohol mixtures is an ideal way to unambiguously characterize these dipeptides, especially since a large body of data has been accumulated for a wide range of dipeptide derivatives examined singly and in model mixtures.

The techniques outlined above allow sequence determination using complex mixtures of degradation peptides without their individual separation. Furthermore, the large amount of data obtained can be interpreted with partial assistance of a computer which can also aid in the assembly of the complete protein sequence. At the present time individual interpretation is involved to a considerable extent, but all the features necessary for a highly automated approach exist. It is expected that during application of this technique to more and more naturally occurring polypeptides of known and unknown structure data and experience will be continuously accumulated to make this approach even more reliable, efficient, and sensitive.

---

*The tryptic peptide samples were donated by M. Elzinga, Boston Biomedical Research Institute, Boston, Mass. and received as lyophilized samples accompanied by amino acid analysis results.

CHEMISTRY AND BIOLOGY OF PEPTIDES

THE USE OF MASS SPECTROMETRY IN PEPTIDE CHEMISTRY

Piet A. Leclercq, P. A. White, K. Hägele, D. M. Desiderio.* The Institute for Lipid Research and Department of Biochemistry, Baylor College of Medicine, Houston, Texas 77025

IT IS NOW EVIDENT that there is an increased need for a new method to obtain the amino acid sequence of biologically active oligopeptides. Due to an increasing number of naturally occurring peptides that are extracted at the microgram level and/or that contain a blocked *N*-terminus, it has been necessary to employ sequencing techniques other than wet chemical techniques such as the Edman method. Examples of both of the above difficulties have been reported.[1,2]

For these reasons, the thrust behind the research done in this laboratory has been towards the sequencing of biologically active oligopeptides on the microgram level by means of mass spectrometry. The limitations of this newer instrumental technique include volatility of the sample and an upper limit of the mass of the peptide of 1000-1500 mass units.

This report will discuss the derivatization of peptides that is necessary to provide sufficient volatility for mass spectrometry (as a rough estimate, it is necessary to have at least 10^{-5} mm vapor pressure at 300°C).

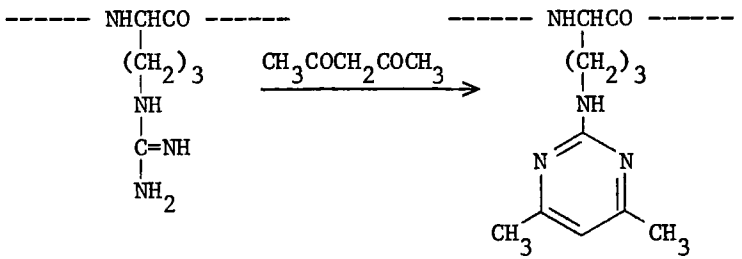
Based upon the pioneering work of Lederer,[3] Biemann,[4] Lande[5] and others, we found that we had to address our efforts to three areas of derivative formation. First,

*Present Address: Department of Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

acetylation had to be performed on the nanomolar level in a reasonable amount of time. Second, the permethylation reaction had to be made applicable at the nanomolar level for all of the amino acids. Third, arginine had to be included in any analysis. While it is true that enzymatic hydrolyses would furnish *C*-terminal Arg peptides, the isolation of a small amount of an Arg-containing peptide would possibly not be amenable to such a technique.

Therefore, the following laboratory procedure has been developed and applied to a wide variety of oligopeptides. The two (or three) step derivatization process has been found to be quite useful:

Step 1. Convert the arginine side chain to dimethylpyrimidyl ornithine by a reaction with acetylacetone.[4]



This reaction has been found to proceed smoothly on the 100 nanomolar level with a nonapeptide such as bradykinin.[6]

Step 2. In order to avoid quaternization during the permethylation reaction, the free amine groups are acetylated. The peptide is dissolved in methanol, dissolution aided with ultrasonic treatment,[7] and acetic anhydride added. The reaction mixture sits at room temperature for three hours. Because such a wide range of reaction times had been reported,[8] we investigated the optimum for this parameter.[9] Reagents are removed under vacuum.

Step 3. *N,O,S* permethylation replaces all hydrogen atoms not bound to carbon with a methyl group. This is accomplished by reacting the peptide with the methylsulfinylmethide carbanion ($DMSO^-$) to produce a peptide polyanion, then adding methyl iodide to effect methylation. The reaction proceeds at room temperature for one hour and is terminated by adding water. The permethylated peptide is extracted with chloroform.

The derivatization reactions above have been employed on a wide variety of oligopeptides. Lys-Tyr-Glu has been sequenced by mass spectrometry with no difficulties.[9] The

N^{α} and N^{ϵ} groups were acetylated and the carboxyl groups and hydroxyl groups methylated. <Glu-Pro-Tyr-His-NH_2 was investigated.[10] The *N*-terminal pyroglutamic acid residue obviates many enzymatic and chemical methods. Also, the proline residue inhibits many enzymes. Histidine was difficult to derivatize[10,11] and the carboxamide group inhibits carboxypeptidase. The *O,N* permethylated peptide yields all sequence information. Methionine was specifically investigated due to the ease of oxidation of the sulfur. No difficulties were experienced with acetylated permethylated Thr-Met and Met-Gly-Met-Met.[12]

Finally arginine-containing peptides were investigated.[6] This is necessary because some natural peptides[13] contain Arg, and sufficient peptide is not always available for enzymatic hydrolysis. All three steps above were necessary to derivatize Arg, Arg-Arg, Ser-Arg-His-Pro and Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg (bradykinin). The sequence was obtained in all cases.

With each mass spectrum discussed above, the amino acid sequence was obtained by means of a computer program adapted from Biemann's program.[14] The input data consist of all peaks in the low resolution mass spectrum and the quantitative amino acid analysis. (In a high resolution mass spectrum, this analysis is not necessary.) All possible sequences are exhaustively searched for and the output lists the more probable sequences. In all cases, the most probable sequence is the correct one.

In conclusion, all of the chemical and instrumental methodology discussed here has been developed out of the necessity of obtaining the amino acid sequence of natural oligopeptides on submilligram quantities. In addition, these peptides usually have a blocked *N*-terminus. As usual, an unequivocal sequence must be obtained in order to synthesize the sequence and to verify the biological activity. Concurrent with the discussed techniques, ancillary methods are being developed. These include peptide synthesis, computer programs to enable finding synthetic model compounds from the literature,[15] and chemical ionization methods to enhance the overall mass spectrometric sensitivity.[16]

CHEMISTRY AND BIOLOGY OF PEPTIDES

THERMAL DEGRADATION OF PEPTIDES TO DIKETOPIPERAZINES AND ITS APPLICATION TO SEQUENCE DETERMINATION

A. B. Mauger. Research Foundation of the Washington Hospital Center, Washington, D.C. 20010.

THE FORMATION OF DIKETOPIPERAZINES during thermal degradation of peptides has various analytical applications, particularly since their gas chromatographic properties have been described.[1,2] The technique reported here involves pyrolysis-gas chromatography, P G C, in which the peptide is held at 400° for 20 sec in the flowing carrier gas. The pyrograms so obtained are reproducible and quantitation can be introduced by addition to the sample of a suitable internal standard. Thus far the only diketopiperazines produced result from adjacent pairs of amino acids in the peptide.

Since dipeptides cyclize readily at elevated temperatures, the P G C method has potential for their quantitative analysis. For example, L-prolyl-L-proline, which is difficult to measure using the amino acid analyzer, was converted by pyrolysis to the diketopiperazine in quantitative yield. It was therefore possible to measure this dipeptide using P G C with an internal standard.

Thermal degradation of tripeptides under comparatively mild conditions was investigated in 1938.[3] Tripeptides with the general sequence ABC generated the diketopiperazine AB and the amino acid C. This reaction can even proceed at room temperature in the case of D-valyl-L-prolyl-sarcosine.[4] Several tripeptides were submitted to the P G C technique. The results are summarized in Table I. With one exception the tripeptides in which glycine is *N*-terminal produced both AB and BC diketopiperazines, with AB predominating. For example, glycyl-leucyl-alanine gave glycyl-leucyl and leucyl-alanyl diketopiperazines in yields of 67 and 23%

Table I

Pyrolysis-Gas Chromatography (P G C) of Tripeptides

Tripeptide	*Diketopiperazines Produced*	
ABC	*AB*	*BC*
H-Gly-Gly-Ala-OH	+ +	+
H-Ala-Gly-Gly-OH	+ +	-
H-Gly-Leu-Ala-OH	+ +	+
H-Ala-Leu-Gly-OH	+ +	-
H-Gly-Phe-Ala-OH	+ +	+
H-Ala-Phe-Gly-OH	+ +	-
H-Gly-Pro-Ala-OH	+ +	-

respectively, for a total of 90% conversion to one or other diketopiperazine. In such cases the data establish the sequence. However, those tripeptides in which glycine was C-terminal produced only the AB diketopiperazine, as did the case in which B was proline. In the latter instance, as in the aforementioned room-temperature reaction, the AB peptide bond can adopt the *cis* conformation, permitting more rapid cyclization.

In early studies on the sequence of actinomycin C_1, valyl-prolyl and sarcosyl-N-methylvalyl diketopiperazines were isolated and identified after thermal degradation in hydrazine hydrate.[5] Assuming that threonine cannot be C-terminal in view of the lactone structure, 16 of 48 possible sequences remained. With the far simpler P G C procedure prolyl-sarcosyl diketopiperazine was identified in addition to the above, reducing the number of possible sequences to two and utilizing only micrograms of actinomycin. Application of this method to novel actinomycins was reported recently.[6] It is noteworthy that N-terminal degradative sequencing procedures cannot be applied to cyclopeptides such as actinomycin, and that in this series mass spectrometry has also been unproductive thus far. In these circumstances the P G C approach to sequence determination is useful.

In extending this technique to peptides in general, various limitations are apparent. Theoretically, if a

diketopiperazine is produced from each adjacent pair of amino acids in the peptide, a minimum of two possible sequences (unless the sequence is symmetrical) result, and the number may be higher where sequential degeneracy exists. In practice, there are limits to the length of peptide chain which will produce all possible diketopiperazines, and there are problems with those amino acids which possess a third functional group. Prior permethylation[7,8] of the peptide provides an approach to solving some of these problems, since polar groups are protected and *cis* peptide bond formation is promoted. Furthermore, gas chromatography of the resulting methylated diketopiperazines[1,9] is far more satisfactory than that of the underivatized compounds.

For the identification of peaks in pyrograms of peptides, comparison of retention times with those of all the possible diketopiperazines is obviously cumbersome. Present studies include the use of gas chromatography-mass spectrometry for this purpose.

CHEMISTRY AND BIOLOGY OF PEPTIDES

AUTOMATED EDMAN DEGRADATION MONITORING OF SOLID-PHASE PEPTIDE SYNTHESIS

Hugh D. Niall, G. W. Tregear, J. Jacobs. Endocrine Unit, Massachusetts General Hospital, and Department of Medicine, Harvard Medical School, Boston, Massachusetts.

MONITORING OF THE COUPLING and deprotection steps in solid-phase peptide synthesis is of the greatest importance in insuring completeness of reaction at each cycle and thus avoiding or reducing the extent of the formation of deletion peptides. No single method yet devised is satisfactory for this purpose. New approaches are needed for both "real time" monitoring during the progress of the synthesis, and "retrospective" monitoring of the purity of the final product, whether still attached to the resin or after purification. We have examined the use of Edman degradation for these purposes, using an automated procedure with radioactive (^{35}S) phenylisothiocyanate, in the Beckman model 890 "Sequencer."

Completeness of Coupling

The method is illustrated in Figure 1. Note that the deprotection step is conveniently carried out in the sequenator cup, using trifluoroacetic acid or heptafluorobutyric acid in 1 chloro-butane. The same reagent can be used for the cleavage step in the Edman degradation. Special programs are necessary, particularly with the Merrifield-type resins, to avoid washout of polymer particles from the cup. Here the "undercut" cup of the most recent Beckman Model 890 "Sequencer" is especially helpful, since the undercut tends to keep the resin particles from

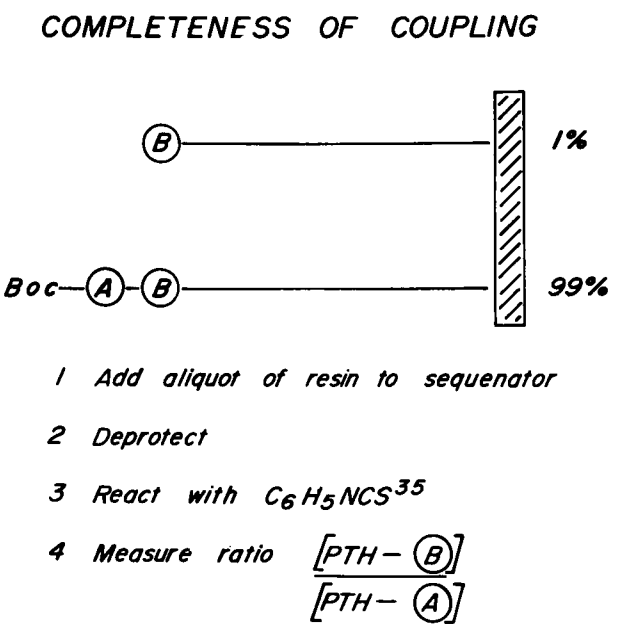

Figure 1: Procedure for monitoring completeness of coupling reaction using automated Edman degradation.

rising up the cup wall. This problem does not arise with the graft copolymer resins developed for solid-phase synthesis[1] since their high density prevents any washout.

Figure 2 shows the results of a degradation cycle on a peptide from bovine parathyroid hormone of sequence Phe-Met-His-Asn-Leu-Gly-Resin, after addition of the phenylalanine. The gas chromatographic tracing of the phenylthiohydantoin (PTH) amino acids obtained shows that *N*-terminal Met is still present at the 3% level, with trace amounts of Leu, Gly and possibly Asn. The ninhydrin test[2] in this case was negative, indicating the greater sensitivity of the end-group approach.

Completeness of Deprotection

Methods for specific monitoring of the deprotection reaction using automated Edman degradation are currently being developed, but will not be discussed here.

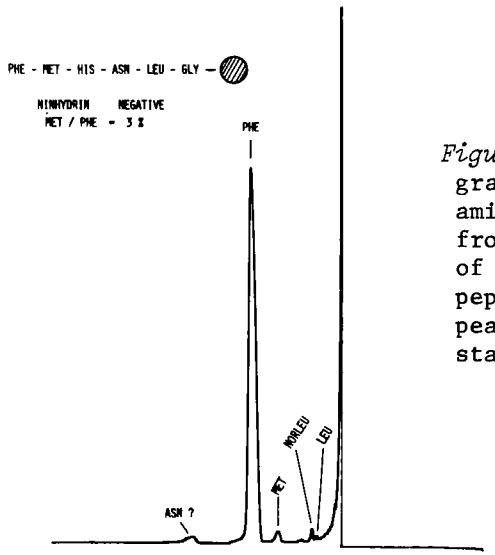

Figure 2: Gas chromatographic tracing of PTH amino acids obtained from a degradation cycle of the solid phase peptide. The norleucine peak is an internal standard. See text.

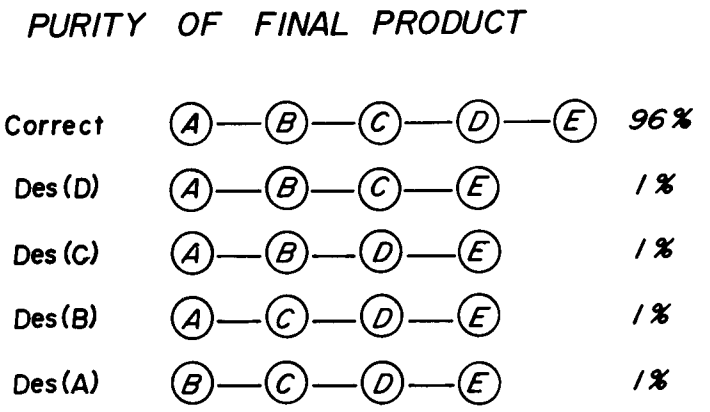
Purity of the Final Product

The rationale of this approach is illustrated in Figure 3. If there is a 1% deletion error at each step in the synthesis of a pentapeptide A-B-C-D-E, then when repetitive cycles of Edman degradation are carried out, the ratio of "wrong" to "correct" amino acid found at cycle 1 will be 1/99, at cycle 2, 2/98, and so on. It can be seen that the ability to detect deletion errors is greatly improved by an "amplification factor" inherent in the Edman method. Thus if the method could not detect an incomplete reaction of, say, 0.5% at any one cycle, the cumulative effect of successive Edman cycles on the final product would soon make the problem obvious.

We have applied this approach to a variety of synthetic peptides produced by the solid-phase approach and have found that deletion errors of the order of 0.5-1.0% per cycle are common even when the ninhydrin test has suggested that the coupling reaction was complete. Incompleteness of deprotection could of course also be responsible.

This approach assumes that the Edman degradation does not cleave off more than one residue at any one cycle. This seems to be true except perhaps for histidine residues for which a premature cleavage reaction has been described.[3]



EDMAN CYCLE	1	2	3	4
RATIO $\frac{Error}{Correct}$	1/99	2/98	3/97	4/96

Figure 3: Application of Edman degradation in assessing purity of a synthetic pentapeptide. Note amplification of deletion errors with successive degradation cycles.

Conclusions

The automated Edman degradation can be used as an effective monitoring procedure for solid-phase peptide synthesis. A single cycle of degradation with identification can be completed in about 2 hours; this time can almost certainly be reduced by appropriate program changes. The method has several advantages over existing approaches. It is quantitative, allowing kinetic measurements. It is direct, since the amino acids with free *N*-terminals are identified directly. It is particularly sensitive in the detection of amino acid deletions in the final product since the errors at individual steps are additive.

CHEMISTRY AND BIOLOGY OF PEPTIDES

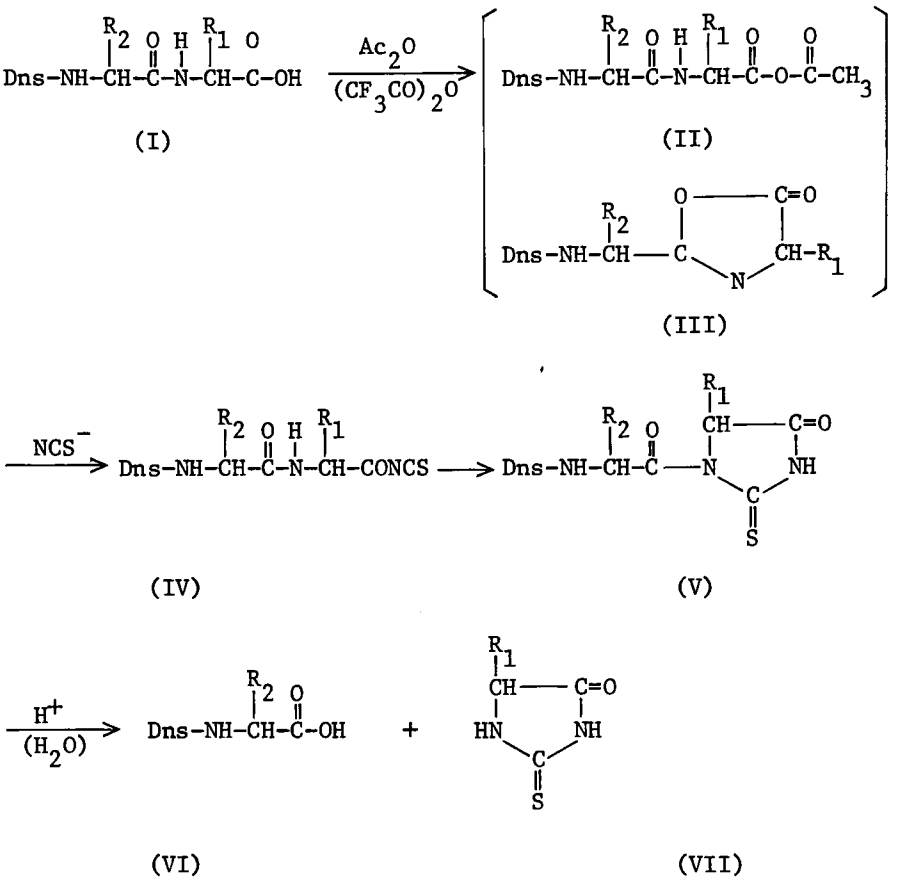
CHEMICAL METHOD OF SEQUENTIAL DEGRADATION OF POLYPEPTIDES FROM THE CARBOXYL ENDS

Saburo Yamashita, Nobuo Ishikawa.* Biochemistry Division, Hoshi College of Pharmacy, 2-4-41 Ebara, Shinagawa-ku, Tokyo, Japan

CHEMICAL SEQUENTIAL DEGRADATIONS of peptides from the carboxyl ends have been one of the interests in peptide chemistry for almost half a century.[1-7] Formation of thiohydantoin rings[8] to selectively cleave peptide bonds at the carboxyl end has been studied. Recently milder conditions have been introduced to improve hitherto employed rather drastic conditions.[5,6] Attention was also directed to minimize the required quantity of polypeptide. This communication deals with the mechanism of thiohydantoin ring formation at C-terminal amino acids, minimization of the quantity of polypeptide, and initial rate of hydrolysis of peptidyl thiohydantoins.

The intermediate C-terminal activated compound must be either II or III, or both. Starting from optically active L-aspartic acid, L-tyrosine, L-arginine, and L-valine, it was found that the optical activity of the resulting thiohydantoins was zero, which might indicate that the thiohydantoin formation proceeds through compound III. Considering the above mechanism and the suggestion of Waley and Watson[2] that the direct formation of acyl isothiocyanate (IV) is desirable to avoid occasional side reactions by the labile oxazolone (III), the use of acetyl chloride[6] to form the mixed anhydride (II) seems to be advantageous. In fact, the yield of thiohydantoins by way of (II)[6] is better than that through (III).[4,5]

*To whom inquiries should be directed.



(I) (II) (III) (IV) (V) (VI) (VII)

Amino acid sequence analysis of polypeptides was successful up to around 10 amino acids from the C-termini,[7] but a rather large quantity (10^{-8} to 10^{-7} mole) of starting material was required, since during the repeated cycles the recovery of the remaining peptide from Sephadex column chromatography was difficult when monitored by the optical density at 280 nm.[7] Thus, the amino terminus of the original peptide was marked by dansylation (I), and the eluate containing the Dns-peptide could be recovered almost quantitatively, and 10^{-8} to 10^{-9} mole of the peptide can be used for the sequence analysis. Dansylation of thiohydantoins (VII) was not successful.

The initial rate of hydrolysis of peptidyl and acetyl thiohydantoin (V) to give VI and VII was studied spectrophotometrically[5] [shift of peak absorption from 280 nm (V)

to 260 nm (VII)]. It was found that the half life of peptidyl thiohydantoin (V) was generally approx. 2 min in 0.1 *N* HCl (comparable to H^+ form of Dowex resin[5] at 25°. Peptidyl thiohydantoins were more rapidly hydrolyzed than acetyl thiohydantoins. The findings may contribute to set up experimental conditions for the sequential analysis of peptides.

CHEMISTRY AND BIOLOGY OF PEPTIDES

THE PRIMARY STRUCTURE OF AN APOLIPOPROTEIN FROM THE HUMAN HIGH DENSITY LIPOPROTEIN FAMILY: ApoLp-Gln-II (ApoA-II)

H. B. Brewer, Jr., S. E. Lux, R. Ronan, K. M. John.
Molecular Disease Branch, National Heart and Lung Institute, National Institutes of Health, Bethesda, Maryland 20014

THE PLASMA LIPOPROTEINS can be classified by ultracentrifugal flotation or paper electrophoresis into four major classes which include chylomicrons, very low density, low density, and high density lipoproteins (HDL).[1,2] HDL isolated by ultracentrifugal flotation (densities 1.063 to 1.21) consists of an approximately equal proportion of protein and lipid.[3] Approximately 90% of the delipidated protein moiety of HDL is composed of two major apoproteins; the remaining 10% is composed of the three major apoproteins associated with the very low density lipoprotein family. The two major apoproteins have been designated as apoA-I and apoA-II, and by their carboxyl terminal residues as apoLp-Gln-I and apoLp-Gln-II.[4-10] Scanu *et al.* have previously reported that the molecular weight of apoLp-Gln-II (designated as fraction IV) can be reduced from 16,000-17,000 to 7,500-8,500 by cleavage of a disulfide bond indicating that the intact apoprotein is composed of two polypeptide chains.[11]

The purpose of this report is to summarize our recent studies on the covalent structure of apoLp-Gln-II.

Materials and Methods

The HDL utilized in these studies was isolated from a single healthy volunteer by ultracentrifugal flotation, delipidated, and fractionated by chromatography on DEAE

cellulose in 6*M* urea.[12] Analytical methods have been previously reported in detail.[12,13] Enzymatic digestion of apoLp-Gln-II with trypsin, cyanogen bromide cleavage, and isolation of the individual polypeptide fragments by ion exchange and gel permeation chromatography has been described elsewhere.[14] Isolated fragments were shown to be homogeneous by disc gel electrophoresis, tlc, amino acid analysis, and Edman amino terminal analysis. Enzymatic digestion of apoLp-Gln-II with pyrrolidonecarboxylyl peptidase (E:S,1:6) was performed in 0.05*M* NH_4HCO_3 (pH 7.8). Following the incubation the sample was lyphilized, and then extracted with acetone or dimethylformamide to solubilize the pyrrolidone carboxylic acid. The extract was evaporated to dryness with nitrogen, redissolved in a small volume of dimethylformamide and identified by mass spectroscopy (Finnigan Quadropole, isobutane carrier gas) or as the trimethylsilyl derivative by gas-liquid chromatography on the CFC blended column at 105°C.[15] Carboxypeptidase A and B digestion (E:S, 1:50) was performed in 0.2*M* NH_4HCO_3 (pH 7.6), and the released amino acids were identified by amino acid analysis.

Manual phenylisothiocyanate degradations were performed by the three stage procedure of Edman.[16] Automated degradations were performed on the Beckman Sequencer (Model 890B). Selected peptide fragments were treated with 4-sulfophenylisothiocyanate prior to automated degradation to increase their hydrophilicity.[17] The phenylthiohydantoin amino acids (PTH amino acids) were identified by tlc,[16] gas-liquid chromatography,[15,18] and mass spectroscopy.[19]

Results

Human apoLp-Gln-II has been isolated to homogenity by ultracentrifugation followed by DEAE cellulose chromatography.[12] The purified apoprotein gave a single band on disc gel electrophoresis (Figure 1A). Following reduction of the cystine residue with 2-mercaptoethanol and carboxymethylation with iodoacetic acid the molecular weight of apoLp-Gln-II (SCMC apoprotein) was reduced from approximately 18,000 to 9,000 by gel filtration in 6*M* guanidine confirming the report of Scanu *et al.*[11] that the apoprotein is composed of two polypeptide chains. The SCMC apoprotein could not be separated into distinct chains by disc gel electrophoresis (Figure 1A), gel filtration, or DEAE-cellulose chromatography.[12] Edman degradation of the intact apoprotein or SCMC apoprotein revealed no detectable amino terminal residue. Digestion of the SCMC apoprotein with pyrrolidonecarboxylyl peptidase revealed the amino terminal amino acid to be pyrrolidone carboxylic acid

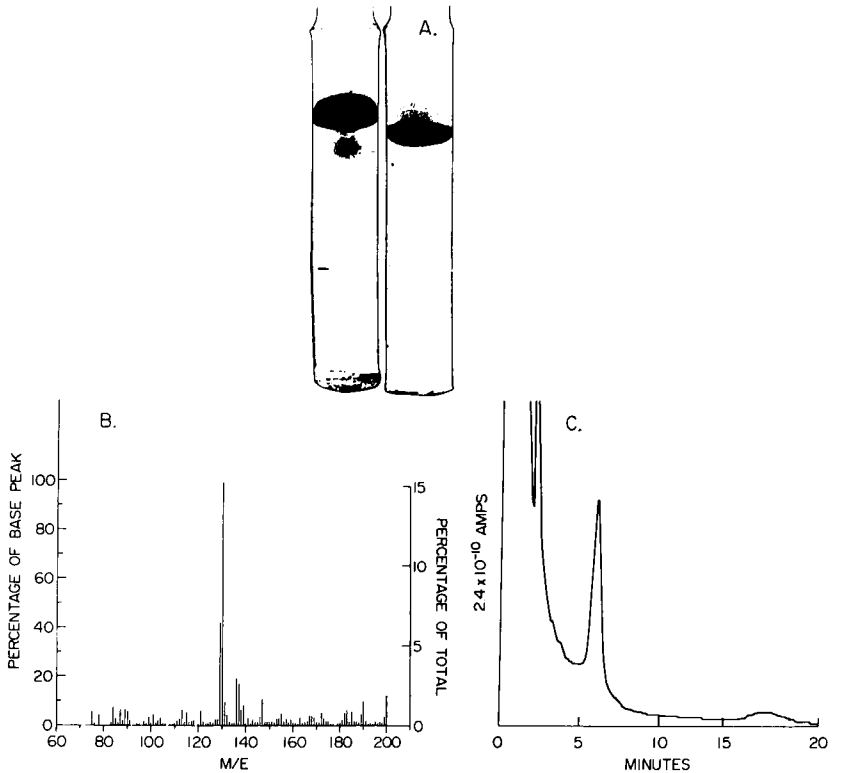

Figure 1: Disc gel electrophoresis (A) of native apoLp-Gln-II (left) and reduced and carboxymethylated (SCMC) apoLp-Gln-II (right); (B) Chemical-ionization mass spectrum and (C) gas-liquid chromatogram of the amino acid residue, pyrrolidone carboxylic acid, released following digestion of SCMC apoLp-Gln-II with pyrrolidonecarboxylyl peptidase.

(pyroglutamic acid) by mass spectroscopy (Figure 1B) or gas-liquid chromatography (Figure 1C). Carboxypeptidase A digestion revealed glutamine as the carboxyl terminal and threonine as the penultimate residue. These combined results which are reported in detail elsewhere indicated that apoLp-Gln-II is composed of two identical polypeptide chains connected by a single disulfide bridge.[12]

The amino acid composition of the SCMC apoprotein was determined by timed acid hydrolysis, and total enzymatic

digestion, and is as follows: $SCMC_1$, $<Glu_1$, Asp_2, Asn_1, Thr_6, Ser_6, Glu_8, Gln_7, Pro_4, Gly_3, Ala_5, Val_6, Met_1, Ile_1, Leu_8, Tyr_4, Phe_4, Lys_9. The SCMC apoprotein contains 77 amino acid residues. There was no detectable carbohydrate on the purified SCMC apoprotein.

Tryptic digestion of the SCMC apoprotein revealed eight major and one minor peptide (Figure 2). The major peptides range in size from a single residue, lysine, T-7, to a 22

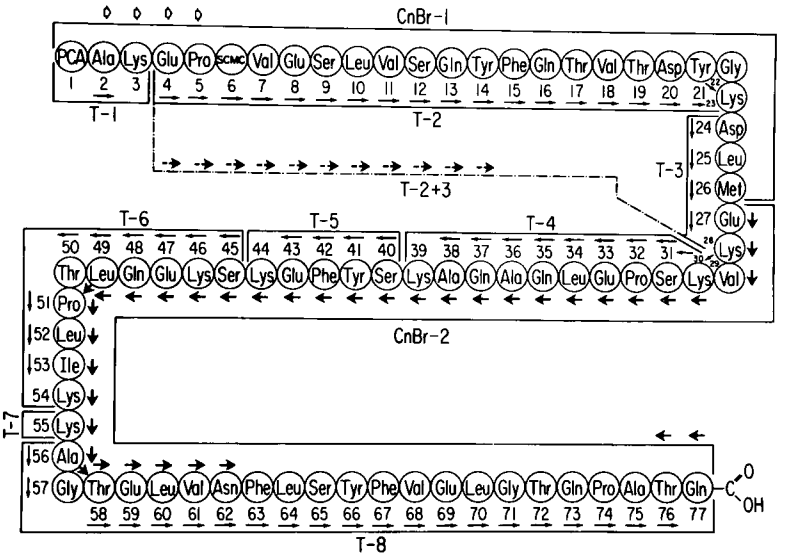

Figure 2: Amino acid sequence of reduced and carboxymethylated apoLp-Gln-II. *Large open arrows* refer to Edman degradations on the apoprotein following digestion with pyrrolidonecarboxylyl peptidase; *small arrows* to degradations on the isolated tryptic peptides; *small dashed arrows* to degradations on tryptic peptide T-2 + 3; *large solid arrows* to degradations on cyanogen bromide peptide CNBr-2; and *large solid arrows* of residues 76 and 77 to carboxypeptidase A digestion of the apoprotein.

amino acid peptide, T-8. The minor peptide was a peptide composed of two tryptic peptides, T-2 + 3. T-1, a tripeptide, contained pyrrolidone carboxylic acid as the amino terminal residue and was designated the first tryptic

peptide; T-8 was devoid of a basic residue, and contained glutamine as the carboxyl terminal residue indicating that it was the carboxyl terminal peptide (Figure 2). Cyanogen bromide cleavage of the SCMC apoprotein produced two peptides, CNBr-1 and CNBr-2. CNBr-1 contained homoserine-homoserine lactone by amino acid analysis, amino terminal pyrrolidone carboxylic acid, and was assigned to the amino terminal position (Figure 2). The amino terminal and carboxyl terminal residue of CNBr-2 were glutamic acid and glutamine respectively indicating that CNBr-2 was the carboxyl terminal cyanogen bromide peptide (Figure 2).

The complete covalent structure of apoLp-Gln-II was determined by manual and automated Edman degradations on the intact SCMC apoprotein, and tryptic and cyanogen bromide fragments. Peptide T-1 was initially digested with pyrrolidonecarboxylyl peptidase, and then degraded by the Edman procedure with PTH alanine being identified as the second residue (Figure 2). Each of the remaining tryptic peptides T-2 to T-7 were degraded both by the manual as well as the automated technique (small arrows, Figure 2). Peptide T-8, the carboxyl terminal peptide, contains no basic residue and was degraded only by the manual procedure (small arrows, Figure 2). The carboxyl terminal residue of each of the tryptic peptides was determined by amino acid analysis following the appropriate number of cycles for each peptide. The alignment of the tryptic peptides T-1 and T-2 was established by digestion of 1.0 μmol of the intact SCMC apoprotein with pyrrolidonecarboxylyl peptidase followed by four Edman degradations (open arrows, Figure 2). In addition, the overlap tryptic peptide T-2 + 3, which contained the amino acids present in peptides T-2 and T-3, was degraded with results consistent with the alighment of the peptides as T-2 followed by T-3 (dashed arrows, Figure 2). An automated degradation of 1.2 μmol of CNBr-2 was performed in order to align peptides T-3 to T-8. This degradation (35 cycles) aligned the tryptic peptides (T-3 to T-8), and confirmed the sequence of the manual degradations on tryptic peptides T-4 to T-7 (large solid arrows, Figure 2). The carboxyl terminal sequence provided by the Edman degradation of T-8 was confirmed by carboxypeptidase digestion of the SCMC apoprotein with the carboxyl terminal residue being glutamine, and the penultimate residue threonine (Figure 2).

These combined results provided a single unique sequence for the SCMC apoLp-Gln-II (Figure 2). The structure for the intact apoprotein, apoLp-Gln-II, is shown in Figure 3.

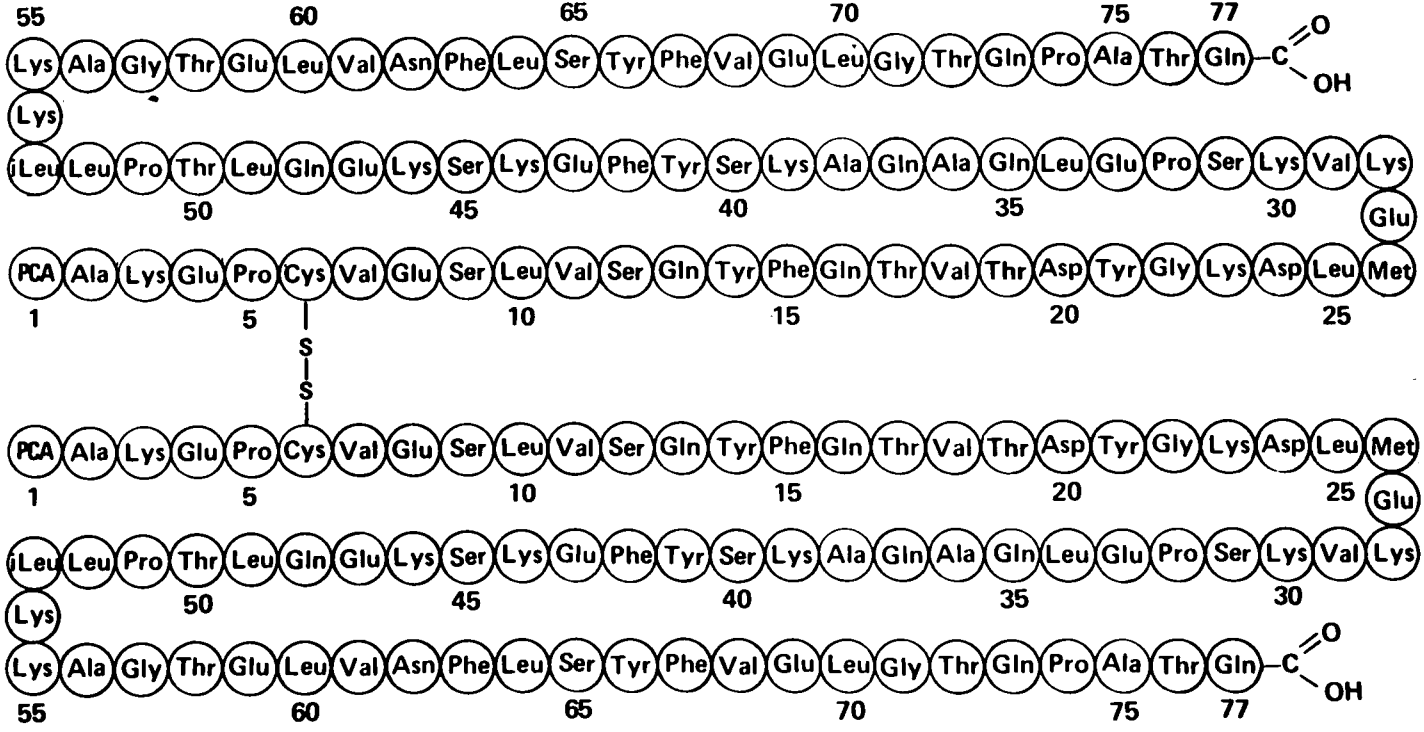

Figure 3: Covalent structure of apoLp-Gln-II (apoA-II).

Discussion

The covalent structure of apoLp-Gln-II is unique in that it contains two identical polypeptide chains. Each chain contains 77 residues connected by a single disulfide bridge at position 6 in the sequence. The apoprotein contains a large number of glutamic acid functions, serine, threonine, and lysine residues, however no tryptophan, histidine, or arginine. The amino terminal residue is pyrroline carboxylic acid, and the carboxyl terminal residue is glutamine. No unique or repeating sequence is present in the molecule, however at a number of positions in the sequence (positions 3,4; 23,24; 27,28; 43,44; and 46,47) a dicarboxylic acid residue is adjacent to a basic residue. ApoLp-Ala, an apoprotein isolated from the very low density lipoprotein family, also has an association of basic and dicarboxylic acid residues (positions 24,25; 51,52; 58,59,60).[20]

The lipid binding site(s) of the plasma lipoproteins is as yet undefined. It is interesting to speculate that the high frequency of paired basic and dicarboxylic acid residues is important in this binding. In this regard, molecular models are compatible with the alignment of the negatively charged dicarboxylic acid with the positively charged choline or ethanolamine, and the negatively charged phosphate with the positively charged amino group of the basic amino acid. Further studies will be necessary to test this hypothesis, and to extend these studies of the plasma lipoproteins to a study of the lipid-protein interactions in membrane proteins in general. In addition, the elucidation of the covalent structure of the plasma lipoproteins will now enable more detailed studies to be performed on the role of this unique class of proteins in lipid transport in normal as well as disease states.

CHEMISTRY AND BIOLOGY OF PEPTIDES

STRUCTURAL STUDIES ON BOVINE PEPSINOGEN AND PEPSIN

Beatrice Kassell, John Kay, Joseph P. Marciniszyn, Jr.
Department of Biochemistry, Medical College of Wisconsin, Milwaukee, Wis. 53233

BOVINE PEPSINOGEN AND PEPSIN have proved to be sufficiently different in composition and specificity from the better known porcine zymogen and enzyme to be of considerable interest.[1,2,3] This report describes the sequence information that has been obtained for the C-terminus of the enzyme and for the peptides released from the N-terminus of the zymogen on activation.

Bovine pepsinogen was isolated as described previously[1] and freed from a trace of extraneous peptides by affinity chromatography[4] on polylysine-Sepharose 4B in 0.05 *M* phosphate, pH 6.5. The pure zymogen was activated at pH 2.0 and 0° for 4 min. The activation mixture was adjusted to pH 3.5 and immediately applied to the affinity column (2.6 x 43 cm), equilibrated in 0.05 *M* formate, pH 3.5. The activation peptides were not retarded and were eluted as one fraction whereas the bovine pepsin was retained by the resin and was eluted with a linear gradient of NaCl.

The peptide mixture was fractionated by column chromatography on Bio-Gel P2 and by high voltage paper electrophoresis. Sequence analysis gave the results shown in Figure 1, with porcine pepsinogen[5] and bovine prorennin[6] included for comparison.

Thus, the N-terminal portion of bovine pepsinogen is much closer in structure to porcine pepsinogen than to bovine prorennin.

Bovine pepsin contains 3 residues susceptible to attack by trypsin.[3] In porcine pepsin, the corresponding susceptible residues are present among the 20 amino acids at the carboxyl terminus, the sequence of which is known.[7]

Figure 2: Partial C-terminal sequences of bovine and porcine pepsins.

Bovine pepsin, prepared as described previously,[4] was denatured[8] at pH 11.2 and 37.5° for 15 min and was digested with TPCK-trypsin at pH 8 for 2 hr at 37.5°. The digestion products were separated on Sephadex G-75 into 4 fractions. The carboxyl terminal portion of 19 amino acids, the sequence of which was determined by Rasmussen and Foltmann[9] was present in the fraction of lowest molecular weight, and resembles the structure of this area of porcine pepsin (Figure 2).

A fraction of intermediate size was purified by ion exchange chromatography. This peptide of 53 amino acids, containing a single arginine residue and corresponding approximately in composition to the penultimate carboxyl terminal region of porcine pepsin,[7,10] was further digested with chymotrypsin at pH 7.8 and 42° for 5 hours. One chymotryptic peptide, containing 21 amino acids, was purified. Part of this peptide resembles a portion of the sequence of porcine pepsin (Figure 2); the substitution of tyrosine for serine involves a single base change. Other peptides are being purified for sequence investigation.

Acknowledgments

This work was supported by USPHS grant AM-09826 and by a grant from the Patrick & Anna M. Cudahy Fund. We are indebted to Dr. Foltmann for sending a copy of his paper before publication.

SYMPOSIUM DISCUSSIONS

Summarized by Johannes Meienhofer

THE LUCID SURVEY about amino acid analysis (S. Moore) and the disclosure of a new fluorometric reagent (S. Udenfriend) were followed by an animated discussion. The audience was reminded of a simple tryptophane determination in hydrolysates by fluorometry after dilution, since tryptophane is highly fluoroescent (excited at 285 nm, fluorescence at 350 nm). No chromatographic separation is required.

The probability was discussed whether a mixture of different components could give the same amino acid analysis as that expected for the pure protein under study, and indeed this was experienced with synthetic trypsinogen activation peptide (Val-Asp_4-Lys); and it is also known to occur with analyses of preparations synthesized by the solid-phase method. As a discussant stated, it is essential for a meaningful evaluation of amino acid analyses of solid-phase synthetic products that (a) all steps of the synthesis are monitored, *e.g.* by titration, and (b) step by step analysis can be done *during* the synthesis instead of afterwards.

As larger and larger peptides are being synthesized a correct amino acid analysis does not necessarily prove homogeneity, if taken as the only criterion. However, that must not be used as an excuse for not determining amino acid analysis at all; rather, this as well as elemental analysis are "*necessary but not sufficient*" data.

The question was raised whether any of the various published procedures for hydrolysis of resin-bound peptides has by now been found to be fully satisfactory, but apparently that seemed not yet to be the case. It was suggested that data obtained by peptide-resin hydrolysis should be checked by data obtained after removal of the peptide from the solid phase by alcoholysis.

A discourse developed on precision of amino acid analysis (to improve on the present 3% maximum deviation would appear to be very difficult) and also on the benefits and dangers of very high sensitivity. Not only do the demands for purity increase when smaller and smaller samples are analyzed, but also natural environmental levels of amino acids start to become a serious source of potential contamination. In current practice (S. Moore) analyses are routinely done at the 10 nanomole level (0.2 ml HCl or CH_3SO_3H and small tubes for hydrolysis) not requiring special purification of acids or blank runs (or stopping to breathe!). Only samples of short supply are analyzed at the 1 nanomole level, and then HCl and H_2O need to be glass-distilled, glassware to be especially well rinsed, and blank runs are required.

Fluorescamine assays, however, can be done at the picomole level (pp 655 to 663). The reagent[1] is also being applied to monitor solid-phase synthesis for completeness of peptide coupling.[2] A discussant wondered whether ninhydrin-negative peptides, as Ile-Arg, would react with fluorescamine; this was not yet known but just under investigation. A number of questions and comments dealt with properties of fluorescamine. The reagent is said to be stable in dry form, not acutely toxic, and gives good color yields even with β-alanine, aspartic acid, also with spermine and spermidine, but not with proline, *N*-methylamino acids, or any other secondary amine. Quenching appears not to be a problem. Excess reagent hydrolyses fast and there is no interfering absorption at 390 nm.

The interesting structure of viomycin (pp 665 to 670) was discussed with respect to its high extinction at 268 nm which has been ascribed to the molecule through synthesis and spectrophotometric examination of model compounds.

The suggestion that α,β-unsaturated amino acids might play a role in the generation of peptides from larger precursors (pp 671 to 678) led to a lively discussion touching on the source of thyrotropin releasing factor formation, nisin oligomerization, addition of amides across keto functions, and a possible separation of LH and FSH releasing activities in LH-RH/FSH-RH.

SECTION X

FORECAST

CHEMISTRY AND BIOLOGY OF PEPTIDES

AN ATTEMPT TO FORECAST THE FUTURE OF PEPTIDE CHEMISTRY

Ralph Hirschmann. Merck Sharp & Dohme Research Laboratories, Division of Merck & Co., Inc., Rahway, New Jersey 07065.

SUMMARY--The problems in forecasting scientific developments in peptide chemistry are briefly discussed. The discussion about plausible future developments includes a brief discussion of the current role of peptides in medicine, possible future application of peptides for ecological purposes and a brief discussion of the impact on peptide chemistry of the recently discovered releasing hormones. The problems in the design of an antagonist of a peptide hormone are briefly considered.

In the field of protein chemistry the synthetic problems are assessed as are problems related to the folding of proteins. An attempt is made to forecast some future developments involving membrane proteins. The lecture concludes with a brief analysis of the unique properties of peptides.

Problems of Forecasting

"Then came the magicians, the astrologers, the Chaldeans and the soothsayers." *Daniel*, IV, 7, *c.* 165 B.C.

Attempting to predict the future of peptide chemistry is at the same time a fascinating undertaking and a hopeless assignment. As scientists engaged in peptide research we find prognostication about peptide chemistry difficult because we tend to predict the future by extending the present. Most of us find it hard to envisage and foresee those developments which are unexpected and which are therefore

often most dramatic in their impact. Thus I believe that my comments this afternoon are likely to fail to predict the most exciting developments of the next 30 years, and are most apt to predict fulfillment of endeavors which have already been initiated. This is not a new dilemma. No one prior to Sumner's isolation of urease in 1926[1] could have predicted that enzymes would prove to be proteins. Similarly the enormous progress in peptide synthesis during the past 40 years became predictable only after Professor Leonidas Zervas, an Honorary President of this symposium, and the late Max Bergmann introduced the carbobenzoxy protecting group in 1932.[2] The effect on peptide chemistry of the synthesis of oxytocin by Professor Vincent du Vigneaud,[3] our other Honorary President, and of the elucidation of the structure of insulin by Sanger[4] is well known to all of us. The point is that once the unexpected has been discovered or accomplished, nearly everyone can predict the next step, but it is unlikely that these developments would have been predictable *a priori*.

Some Plausible Future Developments

Ecology

Since we are living in a society which is becoming increasingly ecology minded, growing cognizance is likely to be taken of the fact that our peptides are biodegradable substances. The fact that Zaoral and Sláma[5] have succeeded in synthesizing an active analog of insect juvenile hormone containing two amide bonds may be viewed as a step in this direction.

Current Role of Peptide Hormones in Medicine. Synthetic Advances.

It is reasonable to assume, however, that the most important developments in peptide chemistry will continue to be tied to biological phenomena. The importance of insulin as a life-saving agent has been recognized for many years and a limited number of other peptide hormones such as ACTH are also enjoying a steadily growing role in medicine. It may take many years before biologists and physicians can determine the clinical value of recently discovered hormones such as calcitonin and of such other biologically-active peptides as nerve growth factor and gastric inhibitory polypeptide, some of which have been discussed at this symposium. It is noteworthy and reassuring that a polypeptide

such as ACTH, or at least one of its fragments, can be synthesized in kilogram amounts. The synthesis of peptides in the molecular weight range of 3000 to 4000 daltons can now be approached with confidence. Often the synthesis entails the combined use of solution chemistry and synthesis on a solid support. Since advances in sequence determination have easily equalled those in synthesis, we have reached the point where *chemistry* is no longer the rate determining step on the road from the isolation of a biologically-active peptide to its clinical use, at least for those compounds with a molecular weight which does not greatly exceed 4,000 daltons. Compared with hurdles such as safety assessment, detailed evaluation by biologists, pharmacologists and clinical investigators, the problems of synthesis are now beginning to be regarded as being among the easiest to solve. We may view this development with some pride, although I suspect that this state of affairs is likely to become also the source of growing frustration on the part of the synthetic peptide chemist, who hopes for rapid clinical acceptance of the compounds which he has been able to synthesize.

Impact of the Releasing Hormones

At recent peptide symposia in this country and in Europe it seemed to some of us that although everybody was working very hard, it was not clear where we were really moving. This year we seem to be more confident about the immediate future of peptide chemistry, and this is due largely, I believe, to the impact of recent developments in the field of the releasing hormones, which have received much attention at this symposium. Compounds such as TRH and LH-RH are active at exquisitely low dose levels, they are of low molecular weight and can be prepared by synthesis in pure form. This is important because, by contrast, the proteins released by these hormones are macromolecules. For example, LH-RH is a decapeptide, but LH is a glycoprotein which has not been sequenced, much less synthesized. Thus a glycoprotein becomes biologically accessible *via* the synthesis of a small peptide. For the same reason the isolation and synthesis of GH-RH--especially human GH-RH--will hold promise for those who are now dependent for normal growth on injections of isolated GH, the supply of which is discouragingly low and the large-scale synthesis of which still seems out of reach. Admittedly, those dwarfs whose pituitaries do not function would not find GH-RH a replacement of GH. It also seems likely that biological surprises will emerge from

research with the releasing hormones. The fact that TRH induces the release of prolactin in man is a case in point. Finally, I should like to suggest that the hypothalamus will not prove to be the last source of novel peptides of biological significance.

Hormone Antagonists. Opportunities and Problems

Peptide hormones are important not only in their own right, but often also because they can be expected to guide us in the design of an antagonist. In some cases the antagonists are likely to be of greater interest than the hormones themselves. Examples of this situation include gastrin, angiotensin II and LH-RH.

I should point out, however, that in general we have been more effective in finding inhibitors of enzymes than antagonists of hormones. The explanation, I believe, lies in the fact that in the design of enzyme inhibitors we can often be guided by knowledge about both the enzyme and its substrate. This is not the case with hormones where our knowledge about the receptor is generally very limited. Indeed, our probing the shape of a receptor *via* synthetic hormone analogs has been compared with the use of a screwdriver by a blind man who seeks to discover the shape of a grand piano. As medicinal chemists we are skillful in systematizing and rationalizing the information about structure-activity relationships which has been accumulated. However, to be able to say that we can truly understand these data, we must be in a position to predict. This is clearly much more difficult and will, in my opinion, require a breakthrough in concept as yet unforeseen. Let me illustrate the complexity of the problem with a recent observation. From the elegant and extensive studies with gastrin analogs by J. S. Morley[6] and his associates at ICI we thought we "knew" that an aspartic acid residue in the penultimate position of the carboxy-terminal end of the molecule is indispensable for gastrin-like activity. The fact that a tetrazolyl analog was fully active nicely supported the proposed receptor model. How startling then was the observation by H. H. Trout and M. I. Grossman[7] that an octapeptide in which alanine replaces the aspartic acid residue stimulates gastric acid secretion. In his effort to gain understanding about receptors, the peptide chemist is no worse off than other medicinal chemists who seek to "see" the receptor with the aid of our currently available tools, both chemical and physical. These tools are likely to seem quite primitive to those who will attend peptide symposia 30 years from now.

Still we must make the most of the methods now at our disposal and it is indeed encouraging that several papers at this symposium reported exciting progress with the synthesis of angiotensin antagonists possessing *in vivo* activity. I believe, therefore, that in the years ahead we shall witness the synthesis of peptides that are hormone antagonists possessing clinical value. This will be a notable advance. I stress "of clinical value" because we in the pharmaceutical industry are acutely aware that compounds possessing only *in vitro* activity have no value in medicine.

Proteins

Challenges of Protein Synthesis

Let us now turn to larger molecules. Enzymes and other proteins will continue to challenge the peptide chemist for many years to come. More than ten years ago Dr. Crick wrote the following about proteins: "In biology, proteins are uniquely important. They are not to be classed with polysaccharides, for example, which by comparison play a very minor role. The main function of proteins is to act as enzymes." The synthesis of molecules possessing enzymatic activity was first accomplished in 1968 and announced simultaneously by two groups in 1969.[8,9] Since that time the syntheses of other enzymes and of growth hormone have been described. These studies have shown that proteins *can* be synthesized but they have also served to focus attention on the shortcomings of existing methodology.

In spite of important advances which have been described since 1969, it is apparent that the synthesis of a pure crystalline protein is still a very formidable undertaking. It seems safe to predict that the synthesis of crystalline enzymes will be announced in the near future. It is possible that this will initially be accomplished through ingenuity in the purification of the synthetic product and its precursors and that the synthesis of a pure protein without excessive recourse to resourceful purification techniques will follow only later on. I have no doubt that advances in synthesis will be forthcoming which will bring about these developments.

Other Challenges of Protein Chemistry

Enzymes will continue to challenge us and our colleagues in other disciplines also from a theoretical point of view. There may be several who feel that they have succeeded in

unraveling the mysterious catalytic powers of enzymes, but I sometimes have the feeling that no two people share quite the same explanation. Surely much remains to be done. Peptide chemists have already contributed significantly to our present understanding of enzyme catalyzed reactions. Semi-synthetic approaches have proven highly rewarding in giving us information about the role in binding of individual amino acids of the protein. It is likely that our understanding will increase rapidly once the *total* synthesis of analogs of enzymes becomes less of an ordeal than it is at present. Another aspect of protein chemistry in which the sea of the unknown is presently very great concerns the folding of proteins. One is confident that the future will see notable advances in this area, although I wonder whether the techniques with which we are familiar today will suffice to permit this breakthrough. We are all aware of the tremendous triumphs which X-ray crystallography has achieved in elucidating the tertiary structure of proteins, but I have always been disappointed that no one seems to be able to look at a three-dimensional model of a protein and say, "Yes, of course! Now I understand the folding of the enzyme, its specificity and its catalytic activity."

Membrane Proteins

In discussing peptides and proteins even as recently as in the late 1960's, the view was generally accepted that nothing would ever be discovered which could rival enzymes in their basic biological importance. After all, the enzymes combine the so-called twin miracles of specificity and catalytic activity and they are required even for nucleic acid synthesis. However, it seems that a rival to the enzymes may be emerging in the form of membranes. It is interesting, I think, that we tend to think of the structural proteins of membranes with the same distaste today with which the majority of chemists--in fact just about everybody except Emil Fischer--regarded peptides 70 years ago. In an informative editorial review published in *Nature* in 1969[10] the proteins of membranes were described as "disagreeable materials." *Nature* went on to say: "Their solubility properties are intractable, and because their native environment is essentially non-aqueous and because they exist in a complex state with lipids, there is no reason to suppose that their physical properties when extracted bear any very close relation to those in the native state." These very appropriate comments should be enough to discourage anyone, but it is apparent that membrane

chemistry is in fact an active, exciting and rapidly expanding field, albeit an extremely difficult one. A recent achievement was the demonstration by Professor Hofmann[11] that a fragment of ACTH which was biologically active also showed high affinity for an adrenal cortical particulate fraction. What molecules could be better suited to interact selectively with cell membranes than peptides? That affinity chromatography, already an important tool of the protein chemist, will continue to play a critical role in the isolation of membrane receptors seems almost a certainty.

Outlook

Those of us who have witnessed the rise and decline of adrenocorticoid steroid synthesis from one of the most active fields of hormone research to one which is at least at present relatively quiescent might well ask whether the same fate might be in store for peptide chemistry as well. I do not think so. There is only so much even nature can do with the cyclopentanoperhydrophenanthrene ring system and there are only so many alkyl, halo and other substituents which even the most imaginative medicinal chemist can attach to this skeleton. On the other hand, using the 20 coded amino acids nature has found a way to build molecules of all sizes and shapes which display a high capacity to interact with each other. The future looks bright, not because we are so clever, but because the building blocks which are at our disposal permit the synthesis of compounds with seemingly unlimited versatility of chemical, physical and biological properties.

CHEMISTRY AND BIOLOGY OF PEPTIDES

THE FUTURE OF PEPTIDE CHEMISTRY: SOME GUESSES AND PIOUS HOPES

J. Rudinger. Institut für Molekularbiologie und Biophysik, Eidgenössische Technische Hochschule, 8049 Zürich, Switzerland

APOLOGIA--Stargazing is a thankless task. Anything I may say will be regarded by some as trite and trivial, or alternatively by others as mere unfounded subjective speculation. Let us therefore agree at the outset: Whatever may turn out to have been right by the time you read this book, was trite and trivial; whatever proves wrong, was unfounded subjective speculation.

Topics

Proteins

In the field of protein synthesis it is my confident hope that tomorrow's deeds will catch up with today's titles, and that we shall truly be able to obtain enzymically active proteins as synthetic substances, in the sense in which we define a substance for our students in their elementary chemistry courses: as materials composed of a single molecular species.

In this field, we seem to have inherited from the organic chemists the lure of total synthesis--the temptation always to aim at the structure of a natural substance. A more modest objective, perhaps less aesthetically satisfying but equally worthy, would be the synthesis of slightly "generalized" enzymes, that is of simplified structures formally derived from the natural enzymes, after considering species variations, modification experiments, and the three-dimensional structure revealed by x-ray analysis, in such a

way as to eliminate as many synthetic complications as possible while maintaining the structures which appear essential. If this should enable us to obtain a *homogeneous* substance with the appropriate enzymic properties, the loss of "naturalness" will have been worth it.

We shall, of course, continue our approach to the protein hormones, always in the hope--by now, well founded in experience--that only a fraction of the sequence might suffice for biological activity.

Natural Peptides

As regards small peptides with biological activity, I would agree with Ralph Hirschmann that there are more fish in the hypothalamus than ever came out of it--and others in intestines, lymphocytes, lungs, amphibian skin, or where you will. One point concerning the practical potential of work on natural peptides may be worth making. Quite often we are told that this or that known or postulated peptide with a given biological activity is "not important": Its activity may appear to be of no practical significance, there may be no known pathology associated with it, its physiological function may be in doubt, or, in the drug industry, the policy-makers may not foresee a sufficient market to make the peptide "interesting." But looking back, we can clearly see that fundamental advances in endocrinology and physiology often became possible only when an active peptide had been made available synthetically in large quantity and adequate purity, and unsuspected opportunities for practical (diagnostic, clinical) application have emerged in consequence. Pointing to this logic of development we can plead also in the future that an apparent overinvestment in peptide research may, at least in some cases, pay off when unexpected and useful applications for its products are eventually found.

Structure-Activity Relations

In the study of structure-activity relations, we are evidently at the beginning of a second wave of synthetic studies on structural modification. Looking back at the first period of analogue synthesis, one could sometimes cry over the waste of synthetic effort which has resulted from the underexploitation or non-exploitation of the products in biology; perhaps a biologist might similarly cry over the uninformative and biologically unimaginative changes which the chemists have sometimes made in the molecules.

The lack of cooperation and even communication has rendered much of this effort sterile. It seems to me--and I hope this is not merely wishful thinking--that in the coming second phase we shall have much better integration of the chemical and biological effort, and a much more rational approach to the whole problem both in the design and in the evaluation of the products. In such an approach I would also see the answer to Ralph Hirschmann's anticipatory bit of gloom about the frustration of the peptide chemist: If the chemist is able to participate vicariously in the thrills of the biological exploration, he need not fear a dull time.

Protein Models

Providing models of proteins has always been an important function of peptide chemistry, whether these were model substrates in the early studies of proteolytic enzymes, or the polymeric models which have taught us so much about the rules of the conformational game and, more recently, about immunogenicity. The model structures are becoming ever more sophisticated; today, as we have seen, the unique advantages of cyclic peptides as conformational models are being vigorously exploited. I believe that this function of peptide chemistry will continue to be important, though some of the ways in which we have contributed in the past have become obsolete through more direct approaches to the structure and properties of the proteins themselves. Looking today at the knowledge of catalytic mechanisms contributed by organic chemists interested in enzymology; at the information on enzyme structures available from x-ray crystallography; and extrapolating the growing confidence with which the conformations of cyclic peptides may be predicted, I think that we shall see renewed activity in the field of highly simplified enzyme models. There has already been some exploration of this field on what one might call the "let's-see-how-far-we-can-get" principle but I suggest that in the next few years we shall see more earnest and perhaps more successful efforts in this direction.

Methods

Isolation

In the work on the smaller biologically active peptides, isolation is to my mind still the most difficult and critical phase and its practitioners have my sincere respect and

admiration. Isolation is still largely an art, but surely there are ways in which it can be made more of a science. One of the most important of these is likely to be affinity chromatography, coupled with immunology since antibodies can in principle provide affinity sorbents which are made to measure. The usual difficulty is the shortage of the isolated material, of sufficient purity, which is required to raise the antibodies in the first place; and when such material does become available, there is always so much that one would want to do with it that one is reluctant to sacrifice it for this one purpose.

Perhaps the dilemma could be avoided by a sort of iterative approach: Use a relatively crude extract, prepared by a sequence of conventional purification procedures, to raise correspondingly heterogeneous antibodies; use and reuse these in the form of an affinity sorbent to accumulate, more simply, further material of the same degree of purity; carry the purification of this material further by conventional techniques; use the more highly purified product to raise a more specific antiserum; discard the first antibody, and use the new one to extract purer material directly from the crude extract; purify this material further... and so on to final purification. This is the sort of procedure I would expect to develop from the interaction with immunology.

Dr. J. Pisano has pointed out to me, and I entirely agree with him, that in isolation work (as in the study of structure-activity relations) we shall have to develop more communication and closer cooperation between the chemist and the biologist: Very often, the bioassay forms the bottleneck in the isolation of a biologically active material and the development of a rapid and convenient bioassay may be decisive for the rate of progress and, indeed, for the success of a project.

Structure Determination

I would not dare to predict the outcome of the competition between ion-exchange chromatography, gas chromatography, and mass spectrometry. I do remember William H. Stein once telling me what a healthy stimulus it had been for the further refinement of ion-exchange chromatography to have mass spectrometry treading on its heels; by the same token, however the race over the next lap may go--and it is going to be neck and neck most of the way--we may expect that it will bring accelerated progress and this can only profit us.

Synthesis

I am often shocked to realize to what extent we are still working essentially by rule of thumb, in spite of the highly advanced state of contemporary organic chemistry in its kinetic and mechanistic aspects. We know very little about the kinetics of coupling even for simple peptides and Klaus Hofmann has pointed out how ignorant we are about the behavior of larger peptides. It is perhaps a hope rather than a prediction that peptide chemists, and perhaps others who appreciate the importance of peptide synthesis, will increasingly contribute to the store of mechanistic or even merely quantitative information on which we can draw to make our syntheses more rational. Normally, the synthetic chemist is of course impatient to get to his product, but I would suggest that occasionally he could save a lot of time by investing a little more of it in systematic study and intellectual effort instead of proceeding by mere empirical experimentation.

One synthetic approach which I confidently expect to develop is the partial synthesis, or relay synthesis, of proteins. It is almost inevitable that we should try to use fragments obtained from readily available natural proteins in combination with synthetic fragments to get modifications of such proteins without having to go through the complete synthesis of the whole peptide chain each time. However, this approach will not be fully effective if we pursue it merely with the methods which happen to be on hand from analytical protein chemistry and classical peptide synthesis. Special degradative and synthetic techniques will have to be developed, or modified for this specific purpose. We have seen a similar development, which is still far from complete, in the techniques of solid-phase synthesis; and indeed, even in classical synthesis tasks of increasing complexity may force us, or should at least stimulate us, to take more trouble over developing methods adequate to a given purpose rather than trying to make do with the most commonly used standard procedures.

On the other hand, the confrontation of conventional peptide synthesis with "non-classical" techniques such as solid-phase synthesis has shown drastically how large a share of our manual labor is taken up by workup and isolation, because of the conditions imposed on us by the varying properties of our products. It is only natural that in "conventional" synthesis, too, we are consciously trying to develop more stereotyped, universal procedures for

manipulating our intermediates, so as to gain some of the advantages of the solid-phase and related techniques while retaining the important assets of solution chemistry. I would expect this development to continue with even greater emphasis.

There is one type of synthetic approach to structure-activity relations which would be anathema to the classical organic chemist but which has some pragmatic justification: What I would call the "subtractive" approach. By this I mean the synthesis of a product, however ill-defined, in which a particular amino-acid residue has been omitted or changed, preferably by omission of a side-chain or functional group, and examination of this product for biological activity. Such a procedure is valid as long as it is used to give a "yes-or-no" answer, or strictly only a "yes" answer: If the product *does* show biological activity, we may fairly conclude that whatever has been left out is *not* essential for activity. Provided we confine ourselves merely to this statement and do not start drawing quantitative conclusions, this seems a perfectly legitimate method of gathering limited information. We might expect to see it increasingly used as suggested by Dr. N. Izumiya, for a preliminary exploration preparatory to the design and more rigorous synthesis of a defined, simplified structure. So much in defense (if defense it needs) of the "subtractive approach."

Purification and Characterization

We have repeatedly spoken about the need for new methods of purifying and characterizing synthetic peptides, particularly large peptides. Such a need does, indeed, exist and the methods will no doubt be developed; but we shall see a good deal of improvement even if those methods which are already available are more extensively and effectively used. To give but one example, immunological criteria are now generally applied by examining the reaction of a synthetic product with antibodies to the purified natural material. This is standing the method on its head. We should be using the synthetic materials as antigens and test by e.g. immunodiffusion if the synthetic product contains antigenic molecules *other* than the natural product. Used properly, I am sure immunological techniques will become increasingly powerful and important in determining the purity of synthetic materials.

I hope we shall be able to develop some degree of consensus about the sort of evidence we shall require before

using terms such as "pure material," "fully identical," or "the synthesis of such-and-such an enzyme." Unless we do this, we shall be misleading others, who take these expressions at their face value, about the state and prospects of our field.

Peptide Symposia

One prediction I can make with complete confidence: In spite of glamorous newcomers such as the prostaglandins, peptides and proteins will continue to be an important and challenging group of substances to the chemist and biologist alike; and for that reason, Peptide Symposia such as this will continue to be exciting and stimulating occasions.

CHEMISTRY AND BIOLOGY OF PEPTIDES

CLOSING REMARKS

F. Merlin Bumpus. Research Division, Cleveland Clinic Foundation, Cleveland, Ohio 44106

DR. FRUTON AFTER HEARING the presentation on scotophobin has pointed out that he, too, has a new biologically active peptide. He has named this "peptidophobin" and threatened that if I talked too long he would synthesize it to "determine its structure."

But more seriously, comments on this meeting should include comparisons of the three peptide symposia which have been held in this country. The first one, which was in 1968 at Yale,[1] was rather limited in scope; dealt largely with sequence determination and synthesis of peptides. Very little work on conformational analysis was presented. The next, in 1970 in Cleveland,[2] was expanded considerably--there was more discussion of conformational analysis; some little time was given to the biologists. This lack of participation by pharmacologists was certainly a weakness of the second meeting. I believe that this has been overcome here; and if I am allowed to star-gaze along with my colleagues, I would suggest that we continue to join with the biologists to obtain a better understanding of the peptide hormone mechanisms.

Another great advance in this meeting was the comment made by Dr. Klaus Hofmann. He recognized solid-phase synthesis. The next step now is for Dr. Bruce Merrifield to recognize fragment condensation. This would almost equal Nixon's recent trip to China.

During the meeting we heard much about conformational analysis, energy minimization techniques, C-13 NMR, CD studies, X-ray crystallography; and to many of us, it was quite a surprise to learn of the "looseness of structure,"

especially of a diketopiperazine. Much was made of the solvent and salt effects, and rightfully so. At times it seemed that with the proper choice of solvents we can each have our own peptide conformation. There will be enough to go around this way.

Fortunately, those in the field of conformational analysis are applying their talents to the simpler molecules; especially to cyclic peptides, and those that are involved in ion binding are extremely interesting. From the papers given at the meeting one must conclude that this interest has led to much work on new methods of cyclization, both by solid-phase and solution methods. We learned about these cyclizations, both when they're wanted or unwanted. We also have been informed about new and better protecting groups, different condensation methods, and polymer modification which may either reduce or increase the degree of cyclization.

Problems related to cross-linking and swelling of resins used for solid-phase synthesis have been discussed. With continued effort along these lines increased yields will result from the solid-phase methods. Methodology for the determination of the completeness of condensation reactions has been discussed. This has not been stressed enough, and I am sure that great progress will be made in this area in the future.

Several new biologically active peptides have been characterized; some have been obtained by modification of structure. One of the interesting things presented was the isolation of a "T" shaped phagocytosis stimulating peptide (Tuftsin); there aren's many chemists able to have a conformation directly from the name of their isolated compounds.

There was much discussion on angiotensin, including the presentation of a new group of competitive antagonists. They'll have tremendous usefulness; I think, possibly, not so much clinically as we had hoped for. New inhibitors to renin, to converting enzyme have been synthesized.

New protecting groups for amines and other functional groups were reported. Many of these will find great use and, fortunately, they are useful for solid-phase as well as for the conventional methods. The new catalysts for condensation are going to be helpful, and I am sure that many of us will adapt these readily.

The previous speakers have discussed the importance of the recent accomplishments in the field of the hypothalamic hormones. It may have been interesting if they had told us more how these are being used on the population problem; possibly that's for our next meeting.

If I'm allowed to make one comment concerning predictions for the future, I would predict that the receptor mechanisms are going to be studied a lot more than in the past. Many people feel that all hormones must act *via* the cyclic AMP mechanism. This may not be necessarily true. Present research in this area of mechanism analysis, only in its infancy, should certainly lead to some very interesting results in the near future.

The Program Committee was very wise in saving the discussion on analytical techniques for the last session. As we constantly heard throughout the meeting there are many problems concerning purity of synthetic peptides. Conclusions concerning the identity of the synthetic product(s) are often too broad and based upon too few criteria of homogeneity.

The methodology that we have heard about here should lend guidance during the next few years and should remind us to limit our claims to that which can be justified by sufficient evidence. I think we're all somewhat guilty from time to time when we are anxious to obtain a biologically active substance synthetically. The use of synthetic peptide analogs for studies on structure-activity relationship has become commonplace. A high degree of homogeneity and exact identity is of utmost importance. As research progresses on interaction of hormone with receptor site, use of pure and properly characterized hormone preparations will become even more important.

And finally, on behalf of all here attending, I think that we owe a debt of great gratitude to Dr. Meienhofer and his Program Committee for planning this meeting. It was well organized. It's been informative and I think we've all had a good time and we'll all be looking forward to the next meeting.

JOHANNES MEIENHOFER, EDITOR

Johannes Meienhofer heads the laboratory of peptide and protein chemistry at the Children's Cancer Research Foundation in Boston, Massachusetts, where he works on compounds of potential interest for cancer chemotherapy.

Dr. Meienhofer studied organic chemistry at the University of Heidelberg in Germany, where he received his Ph.D. degree in 1956. Postdoctoral studies with Dr. Vincent du Vigneaud at Cornell University Medical College in New York, N.Y. (1957-1959) and with Dr. Choh Hao Li at the Hormone Research Laboratory in Berkeley, Cal. (1959-60) stimulated his interest in peptide synthesis, which has since been his main area of research, both at the Technische Hochschule Aachen, Germany (1961-1964) and in his present position. He is a member of the American Society of Biological Chemists, American Chemical Society, Gesellschaft Deutscher Chemiker, and Gesellschaft für Biologische Chemie.
